Abstract. Accurate, unambiguous detection of molecular interactions in living cells via measurements of Förster (or fluorescence) resonance energy transfer (FRET) events is experimentally challenging. We develop and apply a physiological fluorescence lifetime imaging microscopy (physiological FLIM) system to significantly improve FRET detection in living cells. Multiple positive and negative cellular controls are implemented to validate the experimental method developed. FLIM measurement techniques were found to remove fluorescence intensity-based artifacts, resulting in a seven-fold improvement in fluorescence measurement precision. The addition of cellular environmental controls, including both temperature and CO2 stabilization, for physiological FLIM eliminates nonspecific FRET in the live-cell system studied. Overall, only physiological FLIM results in statistically significant results that clearly indicated the presence of specific molecular interactions in the live-cell system. This approach can be applied generally to improve the accuracy and precision of FRET measurements in living cells. © 2009 Society of Photo-Optical Instrumentation Engineers. [DOI: 10.1117/1.3257254]

Keywords: molecular imaging; fluorescence lifetime imaging microscopy; fluorescence resonance energy transfer.

Förster (or fluorescence) resonance energy transfer (FRET) can be used as an in vivo nanoscale ruler to detect the distance between fluorophores or interacting proteins with attached fluorophores. In intensity-based FRET detection, sophisticated calibration and correction procedures are usually required to cope with intensity variations, spectral bleedthrough, back-bleedthrough, and photobleaching. In addition, nonspecific FRET, arising from random collisions of donor and acceptor and/or other unexpected associations of donor and acceptor, affects FRET accuracy, and although it can be detected, it may not be easily removed.

Fluorescence lifetime imaging microscopy (FLIM) retrieves fluorophore lifetime data from fluorescence emission, and can be used to detect FRET with some advantages over intensity-based FRET. Interest in FLIM-FRET is growing, especially as commercial FLIM modules become available for confocal and multiphoton microscopy. However, accurate, unambiguous detection of molecular interactions in living cells remains experimentally challenging due to the presence of nonspecific FRET.

In this study, we develop and apply a physiological FLIM system with experimental controls for CO2 and temperature stabilization to create a physiological environment for live-cell FLIM studies. Our purpose was to investigate how physiological FLIM affects FRET detection in living cells. To accomplish this, we studied a live-cell system involving Ras Homology Protein C (RhoC) inactive-form interactions. RhoC has been identified as a specific oncogene marker of aggressive breast cancer. When active, it is anchored on the cell membrane, interacting with effectors. When inactive, it is bound to its inhibitor RhoGDIγ in the cytoplasm and RhoGDIγ interacts with RhoGDIγ and RhoC caused FRET to occur from the donor (cerulean, attached to RhoGDIγ) to the acceptor (citrine, attached to RhoC) in our experimental cellular group, as in Fig. 1(a). In the positive control cellular group, Fig. 1(b), cerulean was linked to citrine, and therefore FRET must occur. Two negative control cellular groups [Fig. 1(c)] were implemented: cerulean-RhoGDIγ alone, which had no FRET occurring, and cerulean-RhoGDIγ+citrine, which indicated nonspecific FRET. Living CV1 cells (monkey kidney epithelial cells) were either single- or double-transfected with the plasmids encoding corresponding fusion proteins using JetPEX transfection reagent (Stratagene, La Jolla, California).

The time-domain FLIM system employed a tunable picosecond laser for excitation, an ultrafast gated, intensified charge-coupled device (CCD) camera for detection, and achieved 50-ps lifetime discrimination. In this study, cer-
Because cerulean lifetime may decrease under prolonged conditions, significant nonspecific FRET did occur, as indicated by the statistically significant \( p \)-value from the comparison had very small \( p \)-values (\( \approx 4.0 \times 10^{-10} \)), which suggested molecular interactions were detected by FRET, while the comparison of the two negative controls gave a large \( p \)-value (0.93), which suggested that no nonspecific FRET between cerulean and citrine occurred. Without physiological conditions, significant nonspecific FRET did occur, as indicated by the statistically significant \( p \)-value from the comparison of the two negative controls for both FLIM and intensity data (9.43 \( \times 10^{-5} \) and 4.50 \( \times 10^{-3} \), respectively), and thus affected the accuracy of any FRET detected.

Table 1 presents \( p \)-values from \( t \)-test comparisons among cellular groups, pixel data were averaged per cell and two-tailed student’s \( t \)-tests were used. We employed a conventional significance level of 0.1, even though we always obtained much smaller \( p \)-values for stronger confirmation of statistical significance.

Figure 2 compares donor fluorescence lifetime versus intensity measurements for live-cell FRET. Both temperature and CO2 controls were implemented. The donor lifetime values of the experimental cellular group were significantly smaller than the two negative controls (\( p \)-value \( \approx 4.0 \times 10^{-10} \)), indicating FRET. The positive control cellular group (data not shown) also exhibited a shorter lifetime than the two negative controls, as expected. Intensity images, however, exhibited many more inter- and intracellular variations, thereby obscuring the detection of any possible FRET (both specific and nonspecific) occurring in this system. Figure 3 compares the precision of donor fluorescence intensity versus lifetime measurements, as quantified by relative standard deviation (RSD) values obtained from the FRET data in Fig. 2 and reveals the multifold improvement in precision when fluorescence lifetime data were used rather than fluorescence intensity data.
Due to their high variability, intensity-based measurements also led to inconclusive results regarding the detection of molecular interactions. Physiological intensity measurements showed no statistically significant differences between the experimental cellular group and either negative control. The large p-values obtained (0.44 and 0.19) reflected the large distributions of intensities of the FRET donor (Fig. 2) that masked the presence of molecular interactions. We attribute the slightly significant p-value for the negative control comparison (5.67 x 10^-2) to these large intensity variations.

Since the fluorescence intensity-based data presented here were not acquired and processed with sophisticated FRET calibration and correction procedures, the comparisons of intensity and lifetime measurements should not be regarded as comparisons of intensity-based FRET detection and lifetime-based FRET detection. Rather, the key point is that lifetime-based FRET detection is relatively simple to implement and accomplish, without complicated corrections, while still offering statistically significant evidence for FRET.

Non-specific FRET is thought to arise from random collisions and for other unexpected associations of donor and acceptor. Here, CO2 control stabilized the pH value of the cell culture media surrounding the cells at physiological values, and was found to eliminate non-specific FRET in the live-cell FRET-FLIM experiments. Significant non-specific FRET was observed in experiments conducted without CO2 control, when media pH values rose to unphysiological levels. It has been reported that non-specific FRET was absent in a live-cell system when physiological conditions were employed and we further demonstrated that these physiological conditions could be responsible for the elimination of non-specific FRET in live-cell systems. We also observed somewhat higher variability in donor lifetime distributions for all cellular groups when CO2 was uncontrolled (average RSD=4.76%) versus when CO2 control was implemented (average RSD=4.11%). Given the potential influence of pH on protein stability, enzyme and ion channel activity, molecular conformation, and many other cellular and molecular processes, careful regulation of the cellular environment through physiological FLIM offers a valuable tool for FRET studies in living cells.

Implementing physiological FLIM significantly improved FRET detection, clearly and unambiguously indicating the presence of specific molecular interactions between RhoGDI and RhoC in the live CV1 cells studied. The approach described here is generally applicable and should improve FRET detection in a variety of live-cell systems.
