Abstract.

The structure of the antimalarial drug halofantrine is analyzed by means of density functional theory (DFT) calculations, IR, and Raman spectroscopy. Strong, selective enhancements of the Raman bands of halofantrine at 1621 and 1590 cm⁻¹ are discovered by means of UV resonance Raman spectroscopy with excitation wavelength \( \lambda_{\text{exc}} = 244 \text{ nm} \). These signal enhancements can be exploited for a localization of small concentrations of halofantrine in a biological environment. The Raman spectrum of halofantrine is calculated by means of DFT calculations \([\text{B3LYP/6-311+G(d,p)}]\). The calculation is very useful for a thorough mode assignment of the Raman bands of halofantrine. The strong bands at 1621 and 1590 cm⁻¹ in the UV Raman spectrum are assigned to combined C==C stretching vibrations in the phenanthrene ring of halofantrine. These bands are considered as putative marker bands for \( \pi\pi^* \) interactions with the biological target molecules. The calculation of the electron density demonstrates a strong distribution across the phenanthrene ring of halofantrine, besides the electron withdrawing effect of the Cl and CF₃ substituents. This strong and even electron density distribution supports the hypothesis of \( \pi\pi^* \) stacking as a possible mode of action of halofantrine. Complementary IR spectroscopy is performed for an investigation of vibrations of polar functional groups of the halofantrine molecule. © 2010 Society of Photo-Optical Instrumentation Engineers. 1 Introduction

Malaria is a major human parasitic disease and affects approximately 40% of the world population. The mortality and morbidity from the disease strongly increased in the recent decades. The disease has tremendous effects on the economic development primarily of sub-Saharan countries. The control of malaria was declared as a global priority by the World Health Organization (WHO). The main reason for this disaster is a rise of worldwide resistances against existing drugs, most of all against chloroquine. Chloroquine was the mainstay therapy for decades and is one of the most important drugs used against an infectious disease. To address these problems with resistances, more effort is required in the development of novel antimalarials. In particular, a better understanding of the molecular mode of action of the active agents is required for the design of structure-based drugs.

Halofantrine is a drug that is effective against chloroquine-resistant strains of Plasmodium falciparum and Plasmodium vivax. Halofantrine was first synthesized by Colwell et al. in an army research program on malaria, within a large series of phenanthrenes, quinolines, and related arylaminoethanols. The drug is marketed by GlaxoSmithKline under the name Halfan. Halofantrine was also successfully applied in a pediatric study. The drug shows enhanced activity in combination with chloroquine and is especially prescribed against a high incidence of multidrug resistances.

However, the molecular mode of action of halofantrine is not well understood. The drug interferes with the detoxification process of hemoglobin digestion by-products in the 48-h cycle of the red blood cell state of the malaria parasite Plasmodium. It was shown that protein mutations in P. falciparum confer resistances to halofantrine. Recently a crystal structure of a complex of halofantrine and ferrirhoporphyrin IX (FPPIX) was derived and it was found that \( \pi\pi^* \) stacking of the phenanthrene ring of the drug and the porphyrin of the target structure may play a major role in the biological activity. Halofantrine inhibits the formation of the malaria pigment hemozoin. Therefore, a selective binding to...

the small, active growing faces of the hemozoin crystallites may be considered as a mode of action. Halofantrine showed essential chemical features in a pharmacophore model for FPPIX-targeting antimalarials.

New diagnostic techniques are required to elucidate the molecular mode of action of halofantrine in vitro as well as in Plasmodium. Therefore, the fast, easy, and reliable localization of the drug in the biological environment is of high importance. Halofantrine was determined in rat and human plasma by means of high-performance liquid chromatography (HPLC). However, a localization of halofantrine in life cells with high spatial resolution would be desired to address the specific binding sides of the drugs in Plasmodium. Novel photonic diagnostic techniques were recently developed and exciting results were achieved in biomedical research. The application of such biophotonic techniques has high potential to elucidate the molecular mode of action of halofantrine and to contribute in a structure-based design of new, effective drugs against malaria.

2.1 Chemicals

Halofantrine hydrochloride was a kind gift of GlaxoSmithKline and was used without further purification. The systematic IUPAC name of halofantrine is 3-dibutylamino-1-[1,3-dichloro-6-(trifluoromethyl) phenanthren-9-yl]-propan-1-ol. The molecular structure of halofantrine is shown in Fig. 1. The atomic numbering scheme and the partitioning of the phenanthrene ring in P1, P2 and P3 in Fig. 1 is used in the context for the description of the mode assignment.

2.2 Spectroscopy

The Fourier transform (FT) Raman spectrum of halofantrine hydrochloride was recorded with a Bruker FT Raman spectrometer (IFS 100/S) at the macroscopic mode with a spectral resolution of 2 cm⁻¹. The instrument was equipped with a Nd:YAG laser (λ_ex=1064 nm, estimated laser power at the samples of 50 mW) as the excitation source and a liquid-nitrogen-cooled germanium detector.

The complementary FT IR spectrum of halofantrine hydrochloride was measured as KBr pellet using a Bruker IFS 66 spectrometer equipped with a DTGS (doped triglycerinsulfate) detector and with 4-cm⁻¹ spectral resolution.

UV resonance Raman microspectroscopy was performed with an UV Raman setup (HR800 LabRam, Horiba/JobinYvon, focal length of 800 mm and a 2400 lines/mm grating) equipped with an Olympus BX41 microscope, UV sensitive video camera, and a liquid-N₂-cooled CCD detector. For UV microscopy, a UV achromatic fused silica/CaF₂ microspot objective [LMU-40×-UVB, numerical aperture (NA)=0.5] with broad band UVB coating was chosen. Validation of the wave number axis was performed via the Raman signals from Tellur. The excitation wavelength 244 nm was derived from an intracavity frequency-doubled argon-ion laser (Inova300-MotoFREd, Coherent Inc.). The laser power at the sample was estimated to be 1 mW. The spectral resolution was 5 cm⁻¹. Because the laser wavelength was chosen to excite the sample in an electronic absorption band, it was necessary to carefully avoid any sample destruction. Furthermore, the sample rotation technique was applied.

2.3 Density Functional Theory Calculation

Density functional theory (DFT) calculations were performed with Gaussian 03 (revision D.01) with Becke’s three-parameter exchange function (B3) as slightly modified by Stephens et al. coupled with the correlation functional of Lee et al. (B3LYP) and B3 in combination with the correlation part of the functional from Perdew and Wang and Perdew et al. (B3PW91). Double (6-31+G(d,p)) and triple (6-311+G(d,p)) split valence basis sets of contracted Gaussian functions with polarized and diffuse functions were applied. These hybrid exchange correlation functionals provide reliable estimates of experimental frequencies of organic molecules with small root mean square deviations.

The DFT calculated harmonic vibrational frequencies are typically too large compared with the experimentally observed ones, due to neglect of anharmonicity, incomplete incorporation of electron correlation, and the use of finite basis sets. Fortunately, this overestimation of the calculated harmonic vibrational frequencies is relatively uniform and can be circumvented by applying transferable scaling factors to the harmonic frequencies. For the B3LYP/6-311+G(d,p) calculations, values of 0.98 for modes below 1800 cm⁻¹ and 0.96 above 1800 cm⁻¹ were applied, in agreement with the literature.

The calculated Raman activities were transformed into Raman intensities and were further convoluted with Gaussian-Lorentz-weighted profiles to simulate Raman spectra with finite bandwidth.

3 Results and Discussion

Raman spectroscopy has unique capabilities as diagnostic tool in biomedical research. The method is highly specific for slight environmental changes that have importance in the biological activity of molecules—such as changes in pH, water environment or molecular interactions. The measurement is fast and does not require further labeling or preparation steps. The combination of a Raman spectrometer with a confocal microscope enables targeting of biological molecules in subcellular compartments with a spatial resolution of ap-
prox. 0.5 \mu m Living cells can be studied since water is a weak Raman scatterer and the technique is nondestructive. The sensitivity and selectivity of Raman spectroscopy can be further improved if the excitation wavelength is tuned into the electronic absorption of the molecules. Resonance Raman spectroscopy is an extremely capable technique and enables a selective enhancement of the Raman signals of chromophores in complex biological environments.

Furthermore, the application of UV laser excitation wavelengths causes very strong signal enhancements due to the intrinsic enhancement of the scattering effect \( [I(\omega) \sim \omega^2] \) and the resonance enhancement of vibrations that are coupled to the electronic transitions. Additionally, the Raman signals are spectrally shifted with respect to disturbing fluorescence and it is possible to derive Raman spectra with high contrast within an environment with fluorescing background. UV resonance Raman microspectroscopy was applied for a localization of small amounts of antimalarial drugs in plant material.

Fig. 2 (a) UV resonance Raman spectrum of halofantrine \( (\lambda_{exc} = 244 \text{ nm}) \) and (b) FT-Raman spectrum of halofantrine \( (\lambda_{exc} = 1064 \text{ nm}) \). The wavenumber values of some prominent bands are given in graph (b). The band at 1621 cm\(^{-1}\) is very strong in the UV Raman spectrum (a) due to the resonance enhancement. The intensities in both graphs are normalized to the strongest peak in the spectra, respectively.

Fig. 3 Comparison of an experimental FT Raman spectrum \( (\lambda_{exc} = 1064 \text{ nm}) \) of halofantrine (a) alongside a calculated [B3LYP/6-311 + G(d,p)] Raman profile (b). The individual Raman modes of the convoluted profile (b) are shown in the stick spectrum (c). The wavenumber values of some prominent bands are given in (a).

3.1 UV Resonance Raman Spectroscopy

The molecular structure of halofantrine (Fig. 1) shows a chromophoric phenanthrene structure that is highly polarizable and causes strong Raman signals [Fig. 2(b)]. These Raman intensities can be enhanced by several magnitudes by exploitation of the described UV resonance effect. Halofantrine shows strong absorption bands in the deep UV at approx. 250 nm. Therefore, the laser excitation wavelengths \( \lambda_{exc} = 244 \text{ nm} \) was chosen for the investigation of halofantrine. A strong enhancement of two Raman bands at 1621 and 1590 cm\(^{-1}\) is seen in the UV resonance Raman spectrum in comparison with the nonresonant FT Raman spectrum \( \lambda_{exc} = 1064 \text{ nm} \) [Fig. 2(b)]. These strongly enhanced Raman signals of halofantrine can be used as marker bands to localize halofantrine in a complex biological environment. The intensities in the spectra in Fig. 2 are normalized to the strongest Raman peaks, respectively, for better illustration.

3.2 DFT Calculation

3.2.1 Raman spectra

To interpret the individual Raman bands in more detail, a thorough normal mode assignment is required. High-performance computing facilities nowadays enable a reliable...
calculation of vibrational spectra of medium-sized biomolecules. The DFT calculation [B3LYP/6-311 + G(d,p)] of the Raman spectrum of halofantrine in Fig. 3 shows that the band at 1431 cm⁻¹ is underestimated in the calculation. DFT calculations with the hybrid functional B3PW91 were performed to address whether any improvement can be achieved (results are shown in Fig. 4). The calculation with B3PW91 shows an improvement of the intensity of the Raman band at 1431 cm⁻¹; however, the intensity of the band at 1621 cm⁻¹ is overestimated. The results of the DFT calculations with double [6-31 + G(d,p)] [Figs. 4(b) and 4(c)] and triple [6-311 + G(d,p)] [Figs. 4(a) and 4(d)] split valence basis sets are very similar and no significant basis size effect was found. The calculation with the model chemistry B3LYP/6-311 + G(d,p) was chosen for further consideration because of the very good agreement in the wavenumber region 1500 to 1650 cm⁻¹, where certain Raman modes gain strong UV resonance enhancement.

3.2.2 Electron density distribution

The electron density distribution of halofantrine was calculated and yields fundamental insight regarding the possible binding behavior of the halofantrine molecule. A ππ stacking of the phenanthrene ring of halofantrine with the porphyrin backbone of ferritoporphyrin IX (FPPIX) was found in a recent crystal structure of an in vitro complex of halofantrine with FPPIX. One should consider whether such binding is possible, due to strongly electron withdrawing substituents at the phenanthrene ring of halofantrine. The electron density distribution of halofantrine (Fig. 5) highlights the electron withdrawing effect of the substituent’s [C(1)Cl(31) and C(3)Cl(32)] as well as C(27)F(28)F(29)F(30). However, a strong and evenly distributed electron density remains across the phenanthrene ring. This result supports the hypothesis that
ππ stacking may play an important role in the biological activity of halofantrine.

3.3 Mode Assignment and Atomic Displacements

The ultimate goal of the Raman spectroscopic investigation of halofantrine is a localization of the drug at the binding side of the biological target in life cells and an elucidation of changes in the Raman spectrum, caused by molecular interactions. To enable a discussion of such changes in the Raman bands of halofantrine, caused by changes in the environment, a detailed interpretation of the individual Raman bands is required. The DFT calculations can be used for a thorough band assignment. The calculations of the atomic displacements of the molecular normal modes provide much deeper understanding of the associated Raman bands.

The Raman spectrum of halofantrine consists of two well separated parts above 2800 cm⁻¹ and below 1800 cm⁻¹ (see Fig. 6). The range with high wave number values consist of two separated parts: a region with CH-stretching vibrations at the phenanthrene ring (3120 to 3060 cm⁻¹) and an area with CH₂, CH₃ stretching vibrations at the side chain (3010 to 2840 cm⁻¹) of halofantrine. In addition, there is also one OH stretching vibration present at 3710 cm⁻¹. However, the fingerprint region of halofantrine (below 1800 cm⁻¹) is of more importance in the further discussion. The graphical illustration of the atomic displacements of two prominent modes at 1621 and 1349 cm⁻¹ are shown in Figs. 7(a) and 7(b), respectively. The assignment of more Raman bands of halofantrine is summarized in Table 1.

The strongest peak in the UV resonance Raman spectrum (λexc=244 nm) of halofantrine (Fig. 1) is found at wavenumber position 1621 cm⁻¹ [Fig. 2(a)]. This band is assigned to a very strong, combined C—C-stretching vibration at the phenanthrene ring. The atomic displacement of the mode is displayed in Fig. 7(a). The strongest contribution to this normal mode arises from νC(5) = νC(6) in P2 (see Fig. 1 for numbering scheme) as well as from νC(6) — νC(15) at the connection of the side chain of the molecule and δC,C(5)H. A highly symmetric vibration is seen across the phenanthrene ring, where νC(1) = νC(14), νC(3) = νC(4), νC(13) = νC(12), νC(5) = νC(6), νC(11) = νC(10), and νC(7) = νC(8) stretch in phase, with a parallel, out-of-phase movement of the pairs {C(4), C(7)} and {C(12), C(9)} toward each other, respectively. Further bending contributions take place δC=C(14)H, δC,C(11)H and weaker δC=C(9)H and δC=C(8)H. The fluorine atoms F(28), F(29), and F(30) and chlorine atoms Cl(31) and Cl(32) are fixed in space. There are no contributions from the side chain. The very strong enhancement of this mode in the UV resonance Raman spectrum [Fig. 2(a)] is very promising, since this combined C—C-stretching vibration is likely to be influenced by ππ stacking of the phenanthrene ring to the porphyrin ring of biological target structures. The calculation of the electron density distribution of halofantrine supports the hypothesis of such interaction. The monitoring of changes in this Raman band during the drug-target interaction might yield novel insight into proposed biological activities of halofantrine.

The strongest band in the nonresonant Raman spectrum is seen at wavenumber position 1349 cm⁻¹ [Fig. 2(b)]. Two different snapshots of the atomic displacement of this mode are illustrated in Fig. 7(b). The normal mode consists of a very strong, combined CC-stretching vibration at the phenanthrene ring, a in-phase breathing vibration at νC(13), C(7)C(12) of P1, P2, and P3; combined with a deformation mode [see Fig. 7(b)]. The symmetric narrowing of the ring system at νC(13) and νC(12) is nicely illustrated in the two snapshots of the molecular vibration in Fig. 7(b). More contributions to this mode arise from νC(10)C(27) and νC(27)F as well as very strong δC=C(9)H, δC=C(8)H, δC=C(11)H, and medium δC=C(14)H and medium δC=C(2)H, δC=C(5)H, and δC=C(15)H vibrations. Small ωCH₂ contributions are present at the side chain.

3.4 IR Spectroscopy

The IR and Raman spectra of halofantrine yield complementary information. Highly symmetric C—C-stretching vibrations in the phenanthrene ring [[e.g., Figs. 7(a) and 7(b)] possesses strong changes in polarizability and cause intense bands in the Raman spectrum (Figs. 2 and 3). On the other hand, polar

The assignment was performed with help of DFT calculation [B3LYP/6–311+G(d,p)]. The atomic numbering scheme, as shown in Fig. 1, is used for the assignment. The atomic displacements of the prominent mode at 1622 cm$^{-1}$, which is strongly enhanced with UV excitation $\lambda_{exc}=244$ nm [Fig. 2], is shown in Fig. 3. The atomic displacements of the strongest mode in the non-resonant Raman spectrum [Fig. 3] at 1349 cm$^{-1}$ is shown in Fig. 5.
functional groups in the halofantrine molecule cause weak Raman signals, but very strong IR bands. All IR and Raman bands of halofantrine are shown in Fig. 6. The wave number values of some prominent IR and Raman bands are given in the Figs. 6c and 6d, respectively. The strongest IR bands of halofantrine are seen at wave number values 2961, 1320, 1147, 1126, 1082, and 1049 cm⁻¹. The atomic displacement of the very strong IR mode at 2961 cm⁻¹ is exemplarily shown in Fig. 8. This mode represents a combined, asymmetric CH₂/CH₃-stretching vibration in the butyl part of the side chain of halofantrine.

4 Conclusion and Outlook

The vibrational spectra of halofantrine, an active agent against multidrug-resistant strains of the malaria parasite *Plasmodium*, were analyzed by means of nonresonant Raman, UV resonance Raman, and IR spectroscopy as well as DFT calculations. The comparison of the nonresonant Raman spectra and UV resonance Raman spectra showed that distinct Raman bands at 1621 and 1590 cm⁻¹ can be enhanced with excitation wavelength exc=244 nm. UV resonance Raman spectra are many orders of magnitude stronger than conventional Raman spectra due to the ω⁴ dependency of the scattering effect and the selective resonance enhancement. The discovery of these signal enhancements is the basis for continuing experiments that will address a localization of small concentrations of halofantrine in a biological environment. Raman microspectroscopy has unique capabilities to derive molecular information with submicrometer spatial resolution in life cells. It was possible to identify strong, combined C=C-stretching vibrations in the phenanthrene ring of halofantrine by means of a thorough mode assignment of the Raman spectra of halofantrine. These vibrations are considered as putative marker bands for ππ interactions with the porphyrin ring of biological target structures. The calculation of the electron density indicates a strong and even distribution across the phenanthrene ring, despite the electron withdrawing effect of the Cl and CF₃ substituents. The electron density calculation supports the hypothesis that ππ interactions play an important role in the molecular mode of action of halofantrine.

Further experiments are underway to monitor changes of the putative Raman marker bands during the drug-target binding process. These results will shed more light on suggested models for the biological activity of halofantrine. A better elucidation of the molecular mode of action of halofantrine...
will assist in structure-based design of new, effective antimalaria ls.
