Abstract. Raman spectroscopy was performed on optically trapped red blood cells (RBCs) from blood samples of healthy volunteers (h-RBCs) and from patients suffering from \textit{P. vivax} infection (m-RBCs). A significant fraction of m-RBCs produced Raman spectra with altered characteristics relative to h-RBCs. The observed spectral changes suggest a reduced oxygen-affinity or right shifting of the oxygen-dissociation curve for the intracellular hemoglobin in a significant fraction of m-RBCs with respect to its normal functional state. © 2011 Society of Photo-Optical Instrumentation Engineers (SPIE). 1 Introduction

Malaria is often associated with the development of a severe anemic condition in patients, which causes more than half of the mortality resulting from the disease.\textsuperscript{1} The pathogenesis of malarial anemia is complex and not well understood. Since the destruction of the parasitized red blood cells (p-RBCs) can only account for less than 10\% of the overall red blood cell (RBC) loss in malaria patients,\textsuperscript{2,3} the accelerated destruction of the nonparasitized RBCs (np-RBCs) is believed to be the primary cause behind development of the severe anemic condition in patients. The reduced deformability of np-RBCs,\textsuperscript{4–12} which may lead to failure in passing through splenic clearance or phagocytosis by spleen cells due to biochemical changes induced by parasite metabolites,\textsuperscript{2} are some of the factors that could trigger early removal of np-RBCs in malaria patients. Apart from the accelerated destruction of np-RBCs, other factors like dyserythropoiesis or ineffective erythropoiesis, reduced hemoglobin-oxygen affinity or disturbed metabolic pathways in RBCs may also contribute to the development of malarial anemia and the associated hypoxia condition. Further studies on np-RBCs are therefore required to get answers to these questions.

Spectroscopic techniques and in particular Raman scattering has been found to be useful for investigating RBCs in malaria infected blood samples. For example, the use of confocal Raman spectroscopy could shed new lights on the electronic structure of hemozoin, a by-product of hemoglobin (Hb) catalyzation by the malaria parasite and also an important target site for anti-malarial drugs.\textsuperscript{13,14} Significant differences in Raman spectra have been reported for p-RBC and np-RBC in continuous \textit{in-vitro} culture.\textsuperscript{15,16} Therefore, Raman spectroscopy may help in understanding the altered properties of RBCs in malaria patients (m-RBCs). Raman optical tweezers\textsuperscript{17,18} are particularly appropriate for probing subtle changes in m-RBCs as acquisition of Raman spectrum from RBC optically trapped in buffer media helps avoid perturbations arising due to the immobilization of the cells on substrate.\textsuperscript{19} Further, as optical tweezers can trap objects away from cover glass surface, background from the substrate/immersion medium can be effectively reduced compared to typical Raman micro-spectroscopy measurements leading to an improvement in the signal to noise ratio (SNR) of the Raman spectra.

Here, we report a Raman spectroscopy study of m-RBCs collected from patients suffering from the \textit{P. vivax} infection, using Raman optical tweezers. The results show marked differences in the Raman spectra of a significant fraction (∼30\%) of m-RBCs relative to their normal counterpart (h-RBC). These changes are consistent with the possibility that the m-RBCs were incompletely oxygenated, even when they were kept in ambient oxygen, i.e., an excess of oxygen.

2 Materials and Methods

A schematic of the experimental set-up is shown in Fig. 1(a). The 785-nm cw beam from a Ti:Sapphire laser (Mira 900, Coherent Inc.), pumped by a 532-nm diode pumped solid state laser (Verdi-5, Coherent Inc.), was used for both trapping the cells and exciting the Raman spectra. The use of a near infrared laser beam for trapping/excitation reduces the absorption-induced degradation of the RBCs and also helps minimize the fluorescence background. The laser beam was filtered to obtain a smooth profile [Fig. 1(b) and 1(c)] and then introduced into a home-built inverted microscope equipped with a high numerical aperture (NA) objective lens (Olympus 60×, NA 1.42), forming an optical trap. For trapping and acquisition of Raman spectra, we used a laser power of ∼2 mW at the specimen plane. The laser spot size at the focus was ∼1 μm and the RBCs were trapped ∼15 μm above the bottom cover plate of the sample holder. A holographic notch filter (notch filter 1), was used to reflect the 785-nm trapping/excitation beam, which was incident on it at an angle of ∼12 deg. The Raman signal backscattered from the trapped
Dasgupta et al.: Studies on erythrocytes in malaria infected blood sample...

Fig. 1  (a) Experimental set-up. The solid line shows the trapping/excitation beam, whereas the dotted line indicates the Raman signal. For removing high-frequency noise from the laser beam profile, a spatial filter assembly consisting of a pair of convex lenses having 50- and 300-mm focal length and a 50-μm diameter pinhole placed at the focal point of the first lens was used. (b) Original beam profile and (c) the beam profile after spatial filtering, as measured using a monochrome CCD camera.

RBC was collimated by the objective lens and passed back along the same optical pathway. The notch filter 1 transmits the Raman signals above 800 nm, which are then passed through a 100-μm confocal pinhole to reject most of the off-focus Rayleigh scattered light. It was thereafter passed through another notch filter (notch filter 2) that further removes the Rayleigh-scattered laser light. The beam was then focused onto the entrance slit of an imaging spectrograph (Shamrock SR-303i, Andor Technology plc). The spectrograph was equipped with either a 600 lines/mm grating or a 1200 lines/mm grating blazed at an wavelength of 900 nm and incorporates a back-illuminated CCD (iDus DU440-BR-DD, Andor Technology plc) camera thermoelectrically cooled down to −80°C. To allow for observation of the trapped RBC, a green-filtered halogen illumination source and a video CCD camera system were used.

Calibration of the spectrometer was performed using toluene (Spectroscopic grade, Aldrich) and the assignment of the peaks was made from standard spectra. The spectral resolution of our Raman system is about 6 cm\(^{-1}\) with 600 lines/mm grating and the Raman spectra can be recorded in the range from \(\sim 500\) to 2100 cm\(^{-1}\). With 1200 lines/mm grating, the resolution is \(\sim 4\) cm\(^{-1}\) and spectra could be recorded in the range 950 to 1600 cm\(^{-1}\). To remove the presence of the background from the RBC spectra, the background was acquired without a cell in the optical trap. This was subtracted from the original spectra to produce the Raman spectra of the trapped RBC. Further removal of the background could be obtained using the Lieber and Mahadevan-Jansen iterative polynomial fitting method\(^{20}\) for better visualization of the spectra. It is pertinent to note that for all of the analysis presented in the paper, Raman spectra in the region 600 to 1700 cm\(^{-1}\) is used and an identical cropping window of 550 to 1750 cm\(^{-1}\) was used while applying the polynomial baseline fitting. This is done to ensure that nature of the fitted polynomials have minimal variation from spectra to spectra so that the position of zero is closely matched for all of the spectra. As will be discussed in Sec. 3, the spectral changes observed in our study were noted to be related to the oxy/deoxy conformational changes of heme from a planar to a nonplanar form. Therefore, to quantitatively compare the related spectral changes, we normalized the spectra with...
respect to the phenylalanine band (1001 cm$^{-1}$). The choice of a phenylalanine band for the normalization was made because previous studies on the changes observed in Raman spectra of RBCs arising due to oxy-deoxy transitions$^{21-24}$ suggest that the changes in the Raman spectra are primarily in the bands arising due to heme as it undergoes significant conformational changes during the process. It is also pertinent to note here that the changes in the membrane of the malaria affected RBCs (Refs. 2, 4, 10, and 25) can also lead to changes in the intensity of the phenylalanine band. However, previous works suggest that the contribution of membrane proteins to the Raman bands of RBCs is minimum compared to the contribution from intracellular hemoglobin.$^{21-24}$ In view of this, it appears a reasonable assumption that the intensity of phenylalanine band can function as a normalizer. All of the measurements of the peak intensities of the Raman bands were carried out on the normalized spectra.

Blood (1 ml) was collected by venipuncture from healthy volunteers and malaria patients in glass tubes containing ethylenediaminetetraacetic acid ethylenediaminetetraacetic (5.4 mg/3 ml) as an anticoagulant. RBCs were separated from these anticoagulated blood samples by centrifugation at 3000 rpm for three minutes. The separated RBCs were then washed with phosphate buffer saline and suspended in 1.5-mM phosphate buffer containing 290-mM sucrose. This buffer maintains the osmolarity of the suspending media and inhibits the adherence of cells to glass surface.$^{26}$ The cell sample was kept in the open on a laminar flow table (which was earlier sterilized using UV radiation and chemical cleaning of the working surface) for about a one-hour period before recording their Raman spectra. Appropriate dilutions of the cells in buffer solution were then used for experiments.

Raman spectra were recorded from blood samples collected from five healthy donors and five patients suffering from the P. vivax infection. For the malaria samples investigated, the number of p-RBCs, as confirmed from acridine orange staining, was $\sim$1 to 2% of all cells (m-RBCs), and therefore, all of the RBCs studied from malaria infected samples were treated as p-RBC type. While for each blood sample collected from healthy donors, Raman spectra were recorded from $\sim$15 RBCs; for blood samples collected from malaria patients, Raman spectra were recorded from at least 50 cells in each sample. This was done to account for the much larger cell-to-cell spectral variations in the spectra of RBCs from blood samples of malaria patients.

There are several reports$^{21,22,27}$ on photoinduced changes in the Raman spectra of RBC. In the micro-Raman spectroscopic study carried out by Wood et al.$^{21}$ using the same laser wavelength and similar focusing geometry (spot diameter $\sim$1 to 2 micrometer), no photoinduced changes could be observed with 18 mW of laser power for exposure duration up to 200 s. We chose a laser power level of $\sim$2 mW over a time duration of 30 s that is much lower than the safe limit of exposure indicated in previous studies.$^{21,27}$ To further ensure authentic Raman spectra that is not influenced by photoinduced alterations, we carried out time lapsed measurements on the Raman spectra of RBCs at different power levels. The recorded time lapsed Raman spectrum at 2 mW of trap beam power over 30-second period is shown in Fig. 2(C). The time lapsed Raman spectra of trapped RBCs over a period of 30 s and with trapping power of $\sim$2 mW revealed no changes in the spectra or the background level, indicating absence of any photoinduced changes of the cells. This result is consistent with our estimate of the $<1^\circ C$ rise in temperature of the cell for laser power of $\sim$2 mW based on the work of Peterman et al.$^{28}$ At 5 mW laser power, significant changes in the Raman spectra (like increase in the intensity of the Raman bands at 975, 1244, and 1366 cm$^{-1}$ and the baseline offset and a decrease in the intensity of 1546 cm$^{-1}$ band) were observed for exposure time of more than 70 s [Fig. 2(D)]. For 2 mW laser power, no changes were observed even for hundreds of seconds of exposure. Therefore, for all of the experiments reported in the manuscript, the laser power used was 2 mW and the exposure duration was kept limited to 30 s. Notably, the spectra presented in Fig. 2(D) were recorded with the 1200 lines/mm grating and therefore resulted in a slight wavenumber shift of the peaks compared to the spectra recorded using 600 lines/mm grating used in the rest of the experiments. Details of these studies have been presented in our earlier publication.$^{29}$ It is also pertinent to note that cells held under the optical trap can undergo some positional fluctuations, which was estimated to be $<50$ nm ($<1\%$ of cell diameter) for the trap conditions used in our studies. Since RBCs are fairly homogeneous structures, these small fluctuations in the cell position are not expected to contribute to significant changes in the Raman spectra. However, the use of low trap beam power results in poor SNR of spectra recorded from individual cells. To address this aspect, we collected spectra from about 100 cells and used the mean spectrum of each class of cells (h-RBCs or m-RBCs) that had much improved SNR for analysis.

To show the interclass variability of the Raman spectra of h-RBCs and m-RBCs, we show representative Raman spectra collected from five individual h-RBCs and m-RBCs in Figs. 3(a) and 3(b), respectively. The spectra of h-RBCs are similar and display fairly uniform peak distribution and intensities from one cell to another. However, for m-RBCs, large variability was observed. While the spectrum of the $\sim$70% of the m-RBCs was similar to that for h-RBCs, $\sim$30% of m-RBCs show a decrease in the intensity of the low spin (oxygenated-Hb) marker Raman band at 1223 cm$^{-1}$ along with a concomitant increase in the high spin (deoxygogenated-Hb) marker band at 1210 cm$^{-1}$ present in the methine C-H deformation region. We designate the m-RBCs with Raman spectra similar to h-RBCs as nonmodified m-RBCs (nm m-RBCs) and the other as modified m-RBCs (m-m-RBCs). The mean spectrum for h-RBCs, nm-m-RBCs, and m-m-RBCs averaged over all of the spectra collected...

from five healthy donors and five malaria patients is shown in Figs. 4(A)(a)–(c), respectively. One can see the significant improvement in SNR: \( \sim 34 \) dB as compared to \( \sim 22 \) dB for individual cell spectra.

It is worthwhile to note that although the blood samples collected from \( P. \) vivax-infected patients were having \( \sim 1 \) to 2% parasitized or infected cells (the level of parasitemia considered to be significant as per World Health Organization guidelines\(^{30,31} \)), it is well known that apart from the fraction of red cells invaded by the parasites, a large fraction of nonparasitized cells may also have altered characteristics in malaria patients. Such changes may be directly induced by exo-antigens/chemicals released by the parasites\(^{32,34} \) or dyserythropoiesis resulting from the infection.\(^{35,36} \) With the SNR available in the present study, significant changes in the Raman spectra were observed in \( \sim 30\% \) of the red blood cells of the blood samples from malaria infected patients studied in the present experiment.

Apart from the prominent changes observed for methine hydrogen deformation doublet at 1210 and 1223 cm\(^{-1} \), the spectra from m-m-RBCs show changes in Raman bands at 1366/1356 cm\(^{-1} \) (\( \nu_4 \)) and the spin marker bands in the region 1500 to 1700 cm\(^{-1} \). In Table 1, we show the assignment of these Raman bands based on the work of Abe et al.\(^{37} \) and Wood et al.\(^{21} \)

In Fig. 5, we show a scatter plot of the intensities of the Raman bands at 1210 and 1223 cm\(^{-1} \), 1356 and 1366 cm\(^{-1} \), and 1546 and 1636 cm\(^{-1} \) for h-RBCs and m-m-RBCs. The left
Fig. 3 Representative Raman spectra as collected from (a) h-RBCs and (b) m-RBCs. Each of the spectra were acquired over 30 s with ∼2 mW of excitation at 785 nm. All of the spectra were smoothened using a Savitzky-Golay filter for removal of noise. The spectra from h-RBCs show nearly uniform spectral characteristics. However, the Raman spectra from a significant fraction of m-RBCs have characteristics different from that of the h-RBCs. The most noticeable changes in methine deformation bands at 1210 and 1223 cm\(^{-1}\) are indicated by arrows.

column shows the intensities of these bands in the mean Raman spectrum obtained from m-m-RBCs and h-RBCs. In the right column, the normalized intensities of the Raman bands for all h-RBCs and m-m-RBCs studied are presented to show inter- and intraclass scatter in data. Notably, the numbers presented in the scatter plots are the peak intensities of the relevant Raman bands. Since the Raman bands at 1210 cm\(^{-1}\), 1223 cm\(^{-1}\), and 1356 cm\(^{-1}\), 1366 cm\(^{-1}\) in Figs. 5(a) and 5(b), respectively, have well separated peaks, the peak intensities of these bands measured directly from the spectrum were used in the related scatter plots. However, the eight spin marker Raman bands in the region 1500 to 1700 cm\(^{-1}\) are closely spaced and strongly overlapped. The peak position of these bands cannot be determined directly from the spectra. In this case, multiple peak fitting was applied. The previous reports by Wood et al.\(^{21,23}\) show that the Raman spectrum of RBCs is dominated by intracellular Hb and that Hb Raman spectrum in the range 1500 to 1700 cm\(^{-1}\) has eight bands that can be denoted as \(\nu_{38}, \nu_{11}, \nu_{19}, \nu_{37}, \nu_{(C=C)}_{vinyl}, \nu_{(C=C)}_{vinyl}, \nu_{10}, \) and Amide I \(^{21,23}\). Eight Lorentzian peaks allowed independent variation in terms of intensity, width and position were used to obtain the best fit profile to the experimental data. It can be seen that the fitted profile approximate quite well with the observed data. Therefore, the peak intensities of the fitted Lorentzian profiles were used in the related scatter plot.

The ratio between the Raman bands at 1210 and 1223 cm\(^{-1}\) in the mean spectrum from m-m-RBCs were observed to have an average value of ∼1:0.79, different from the value of 1:1.13 observed in the mean spectrum from h-RBCs [Fig. 5(a)]. The intensities of the Raman bands for each h-RBCs and m-m-RBCs are shown in the right column. The relative intensities of the Raman bands can be clearly seen to be well distinguishable for the h-RBCs and m-m-RBCs. Further, for mean Raman spectra from m-m-RBCs, we also observed partial shifting of the Raman band at ∼1366 to 1356 cm\(^{-1}\) in comparison to h-RBCs mean spectra [Fig. 5(b)]. The intensities of 1356 and 1366 cm\(^{-1}\) Raman bands for each h-RBCs and m-m-RBCs are shown in the right column. For spin marker bands in the 1500 to 1700 cm\(^{-1}\) region, major changes can be seen for the 1546 cm\(^{-1}\) peak (\(\nu_{11}\)) and 1636/1633 cm\(^{-1}\) peak (\(\nu_{10}\)) and, therefore, intensity for these peaks for each h-RBCs and m-m-RBCs are shown in the right column of Figs. 5(c) and 5(d). While intensity of the peak at 1546 cm\(^{-1}\) is found to be enhanced in the case of m-m-RBCs with respect to that for h-RBCs, the opposite can be seen for the Raman band at 1636 cm\(^{-1}\). The 1636 cm\(^{-1}\) band for h-RBCs was
also found to be shifted to 1633 cm\(^{-1}\) in the spectra from m-m-RBCs. However, this shift is below the resolution of the set-up (6 cm\(^{-1}\)) and thus not significant. The differences in intensity ratios for the Raman bands between h-RBCs and m-m-RBCs were found to be significant to a \(p\) value of <0.05 for all cases (a–c).

The available Raman data of model porphyrin compounds\(^{37,38}\) suggests that the abovementioned changes can be attributed to changes in the oxygenation status of the intra-erythrocytic Hb. The most striking change in the spectra recorded from m-RBCs is the change in the ratio of the intensities of the 1210 and 1223 cm\(^{-1}\) peaks. While Salmaso et al.\(^{39}\) have assigned the 1223 cm\(^{-1}\) band to \(\nu_{13}\) and the band at 1210 cm\(^{-1}\) to \(\nu_{5} + \nu_{8}\), the 1223 cm\(^{-1}\) has also been assigned to \(\nu_{42}\). These modes are associated with C-H in plane vibrations of methine hydrogen. Proximity to the protein subunits influences the deformation angle and consequently a change in intensities between the planar oxygenated (oxy-Hb) and nonplanar deoxygenated (deoxygen-Hb) Hb structure. It is known that the doublet located at 1245 and 1223 cm\(^{-1}\) in the spectra of low spin heme (oxy-Hb) get shifted to 1223 and 1210 cm\(^{-1}\) in the spectra of high spin heme (deoxygen-Hb).\(^{21,24}\) Studies carried out on RBCs subjected to periodic oxygenation and de-oxygenation cycles have also revealed significant enhancement of the intensity of the 1210 cm\(^{-1}\) band for deoxy-Hb.\(^{21}\) Therefore, observed elevated intensity at 1210 cm\(^{-1}\) for m-m-RBCs over h-RBCs suggests a complete or partly deoxygenated state of a significant fraction (<30%) of the m-RBCs in \(P.\) vivax-infected blood samples.

It is pertinent to note that the RBCs used in our experiments were collected by venipuncture and will therefore be initially in an anemic condition.\(^{35}\) Such dyserythropoiesis may often consist or ineffective erythropoiesis has been reported in adults with anemic malaria, which correlated well with the severity of the anemic condition.\(^{36,44}\) The RBCs collected from malaria patients and healthy persons were suspended in an identical phosphate buffer solution (pH 7.4) to record the Raman spectra. Therefore, a pH change induced shift of oxygen dissociation curve cannot account for the observed spectral changes. Another potential cause that can effect an altered Hb-oxygen affinity is the intracellular concentration of 2,3-Diphosphoglycerate (2,3-DPG), an important metabolite in RBCs, involved in the stabilization of the deoxy-form of Hb. Also, dyserythropoiesis or ineffective erythropoiesis has been reported in adults with \(P.\) vivax malaria, which correlated well with the severity of the anemic condition.\(^{35}\) Such dyserythropoiesis may often consist of megaloblastosis,\(^{36,44}\) which has been known to be associated with an increased level of 2,3-DPG and consequent decrease of Hb-oxygen affinity.\(^{45}\)

Fig. 5 Raman bands showing significant intensity differences in the spectra recorded from m-m-RBCs over that recorded from h-RBCs. Left column: (a) and (b) Relative intensity of bands in the mean Raman spectra of h-RBCs (dark line) and the mean spectra for m-m-RBCs (faded line). The mean Raman spectra (dark line) for \( \sim 1500 \text{ to } 1700 \text{ cm}^{-1} \) region and the fitted peaks for (c) h-RBCs and (d) m-m-RBCs are shown. Right column: Scatter plot showing intensities of the Raman bands for all of the h-RBCs and m-m-RBCs studied. It can be seen that the Raman band intensities for h-RBCs and m-m-RBCs are well separated.
4 Conclusion

Employment of Raman optical tweezers facilitated means for single-cell level evaluation of the oxygenation state of the RBCs from malaria patients. The Raman spectroscopic studies carried out on optically trapped red blood cells collected from blood samples of healthy volunteers (h-RBCs) and from patients suffering from the P. vivax infection (m-RBCs) reveal that a significant fraction of m-RBCs produced Raman spectra with altered characteristics relative to h-RBCs. The observed spectral changes suggest a reduced oxygen-affinity or right shifting of the oxygen-dissociation curve for the intracellular hemoglobin with respect to its normal functional state. Recently, P. vivax malaria has been reported to cause a severe anemic condition and acute respiratory distress syndrome in patients, which may result in a hospital stay and even mortality.46,47 Raman spectroscopic study of m-RBCs in blood sample of P. vivax-infected patients may provide a useful means for estimation of complication that may result from altered oxygen loading capability of RBCs in malaria patients.
