1 Introduction

Renal tumors, whose incidence ranked second only to bladder tumors in the urogenital system cancers, is one of the most common cancers in humans.1 According to statistics, the death rate of renal cell cancer has reached about 40%.2 The same to other cancers, the nature of a renal tumor is hardly predictable.3 At present, the detection methods of renal tumors, including hematuria detection,4 X-ray angiography,5 ultrasound scan,6 computed tomography (CT) scan,7 and functional optical coherence tomography8 are unable to respond to the molecular death rate of renal cell cancer. Principal component analysis is used to classify the Raman spectra of renal tumor tissue and normal tissue. © 2012 Society of Photo-Optical Instrumentation Engineers (SPIE). [DOI: 10.1117/1.JBO.18.3.031103]

Keywords: Raman spectra; renal tumor tissue; molecule variations; tyrosine.

In our study, a confocal micro-Raman spectroscopy with high resolution and spatial filtering ability is used to detect the molecular variations in human RTT. The normal renal tissue (NRT) is taken for Raman scanning to compare with the Raman spectra of RTT. With the help of high-quality, confocal micro-Raman spectroscopy, the low fluorescence background and highly sensitive Raman spectra of RTT and NRT are obtained, which give us more details about molecule variations in renal tumors.

2 Materials and Methods

2.1 Sample Preparation

Tissues samples were obtained from surgical specimens of renal tumor patients. Fresh RTT and NRT were immediately stored in a bottle of liquid nitrogen until Raman spectroscopy measurement. A total of 25 patients (15 male, 10 female; age 42 to 68, mean 54.6 years) diagnosed with a renal tumor by an experienced clinical pathologist, were provided by Sun Yat-Sen Memorial, Sun Yat-Sen University, and Nanfang Hospital,
Guangzhou, China. Figure 1 is a typical male patient with a renal tumor in our experiment (provided by Nanfang Hospital). Figure 1 is a section of a histology image stained by hematoxylin-eosin (H&E staining), which is a common staining method in clinical pathology. In Fig. 1, the renal cells have a rounded or polygonal shape and abundant clear or granular cytoplasm, which contains glycogen and lipids. The nuclei are small, round, deeply stained, and located on the edge or center of the cell. Informed consent was obtained from all subjects, and the study was approved by the medical ethics committee of Nanfang Hospital, Southern Medical University.

Five-millimeter square tissue samples without any slicing were placed on a silicon slice for Raman scanning; there are no extra Raman peaks in the region of 700 to 1800 cm\(^{-1}\) on the silicon slice. In order to avoid the dehydration caused by the dry environment in a Raman laboratory, and ensure the focus position did not change in the testing process, samples were infiltrated by normal saline. The concentration of saline solution used was 0.9\% (weight/volume, W/V), which is an osmotic solution with the human tissue.

2.2 Confocal Micro-Raman Spectroscopy

Confocal micro-Raman spectroscopy, which is a nondestructive technique, provides information about the molecular composition, molecular structures, and molecular interactions in cells and tissues. Raman measurements were performed using a Renishaw (New Mills, UK) inVia confocal micro-Raman spectroscopy equipped with a 785-nm laser. A Leica microscope objective (DM2500) of magnification 10x was used to focus the incident laser light on the solution in a capillary tube approximately 1 mm in diameter, and to collect the backscattered Raman light with a detection range of 700 to 1800 cm\(^{-1}\). The laser power focused on sample was \(\sim 11.7 \text{ mW}\), and the acquisition time of each spectrum was 30 s. The slit-width used is about 50 um. All data were collected under the same conditions. Before Raman scanning, the instrument is calibrated by silicon at the 520-cm\(^{-1}\) band.

2.3 Data Analysis

For each sample, at least 25 Raman spectra are obtained. In order to compare the related spectra change, the band intensity at 1003 cm\(^{-1}\) (assigned to phenylalanine) is used to normalize the spectra. The final Raman spectrum of each sample is baseline corrected by the software R 2.8.1, which is provided by Renishaw, and smoothed, normalized, and averaged by Origin Pro 7.5 (OriginLab Corp., Northampton, MA). Statistical Package for the Social Science (SPSS) was used for statistical analysis in this study (SPSS 17.0, SPSS Inc).

The spectra recorded from RTT and NRT are statistically analyzed by principal component analysis (PCA). PCA is oriented toward modeling a variance-covariance structure of a data matrix from which the eigenvalues, corresponding to principal components, are extracted. Each principal component (PC) is a linear combination of the \(n\) independent wavenumber variables \(x_1, x_2, x_3, \ldots, x_n\). For example:

\[
PC_1 = a_1 x_1 + a_2 x_2 + a_3 x_3 + \ldots + a_n x_n.
\]

The first PC accounts for the greatest variance which corresponds to the largest eigenvalue. The second PC is orthogonal to the first, with each successive PC being both orthogonal to all those preceding, and accounting for a decreasing proportion of the variance. In this paper, we chose the first three PC which has accounted for more than 75\% of the accumulative total contribution for analysis.

3 Results

3.1 Raman Spectrum of Normal Renal Tissue

A typical Raman spectrum of normal renal tissue is shown in Fig. 2. The primary Raman peaks of NRT are observed at 831, 855, 936, 1003, 1340, 1450, and 1661 cm\(^{-1}\). The doublet of fermi-resonance caused by breathing vibration of a tyrosine hydroxyphenyl ring and in-plane bending vibration of octave are observed at 831 and 855 cm\(^{-1}\). Raman peak of 936 cm\(^{-1}\) is assigned to amide I. Complete Raman frequency assignments of NRT spectrum are presented in Table 1.

3.2 Raman Spectrum of Renal Tumor Tissue

All the Raman spectra of RTT have been baseline corrected, smoothed, normalized, and averaged a final spectrum (Fig. 3).
In the low region (800 to 1000 cm\(^{-1}\)), compared with NRT, the Raman intensity of RTT enhance significantly. These enhanced Raman peaks include 831, 784, 1087, and 1130 cm\(^{-1}\). As the intensity of Raman peaks present the content of molecule composition, the intensive peaks at 784 and 1087 cm\(^{-1}\) show an increase content of PO\(_2^−\), which is related to nucleic acid.\(^{27}\) At the same time, the intensive 1130 cm\(^{-1}\) band shows a higher content of C–N stretching vibration. In addition to low region, intensive Raman peaks also can be found at 1340, 1450, and 1661 cm\(^{-1}\) in the RTT spectrum, which indicate the increased content of protein and collagen. Compared with the Raman spectrum of NRT, peaks at 851, 1242, and 936 cm\(^{-1}\), which belong to fermi-resonance of tyrosine, amide III, and the C–C bond, respectively, revealing a decreased tendency.

3.3 Principal Component Analysis

In this study, PCA is used to distinguish the Raman spectra of RTT and NRT. Result is shown in Fig. 4, which depicts the plot between scores of the first principal component (PC1) and the second principal component (PC2). Twenty-seven Raman spectra of NRT and 28 Raman spectra of RTT are used for PCA. The plot shows that almost all the Raman spectra of RTT locate at bottom left. And the Raman spectra of NRT are at the opposite in Fig. 4. The analysis result shows a good classification compared with other method.\(^{18}\)

4 Discussion

Despite all the progress made over the last decades, cancer remains a leading cause of death and its natural course is difficult to predict in a single patient. Fortunately, Raman spectroscopy can provide a total simultaneous chemical analysis (on lipid, protein, and nucleic acid), and the change that display on Raman spectra can be used as the marks of tumors. For the specificity of tumor cells, the tumor tissue has many differences from the normal one such as shape, organizational structure, and tissue constituents. Compared with the normal tissue, the tumor tissue contains more protein, collagen, mucus, and nucleic acid.

From Fig. 3, we see the most dramatic change in the Raman spectrum of RTT are observed at 788 and 1087 cm\(^{-1}\), which originate from symmetric ($\nu$PO\(_2^−\)) and asymmetric ($\nu_a$PO\(_2^−\)) stretching bands of phosphodiester groups.\(^{28}\) In the NRT Raman spectrum, there is no obvious Raman peak at 788 cm\(^{-1}\). While in the spectrum of RTT, this peak has a notable increase. Meanwhile, the peak of 1087 cm\(^{-1}\) also increases sharply in RTT spectrum. These results agree well with the findings of Wong et al.\(^{8,20}\) and Rigas et al.\(^{30}\) In the RTT, most PO\(_2^−\) groups become hydrogen bonded, and intermolecular packing among neighboring PO\(_2^−\) groups becomes closer. These results point out that nucleic acids are mainly responsible for the observed change in $\nu$PO\(_2^−\) and $\nu_a$PO\(_2^−\) bands.\(^{28,30}\) Since much information is concerned with structural change of nucleic acids in tumor tissue, peaks at 788 and 1087 cm\(^{-1}\) can be used as the RTT markers for Raman detecting. Moreover, study of 788 and 1087 cm\(^{-1}\) is potentially significant for understanding other cancers; we seek to confirm the molecular variations origin of the phosphodiester stretching modes in the Raman spectra of tissues and cells.

In addition to $\nu$PO\(_2^−\) and $\nu_a$PO\(_2^−\) groups, the Raman bands at 831 and 855 cm\(^{-1}\), which correspond to tyrosine, also obviously change. In NRT spectrum, the peak at 831 cm\(^{-1}\) is inconspicuous. However, there is an obvious peak at this Raman shift in RTT, but another peak belongs to tyrosine which appears at 855 cm\(^{-1}\), which shows a different tendency (Fig. 5). Because the ratio $I_{855}/I_{831}$ is relevant to the environment of tyrosine residue, it is used to estimate the conformational change of tyrosine in tumor tissue. When –OH bands, which locate in benzene rings of tyrosine, combine with H\(_2\)O, we regard the tyrosine conformation as “exposure” according to previous research.\(^{31}\) If these –OH bands combine with –COOH bands which locate in the protein residue, the tyrosine conformation is said to be “buried”. For the “exposure” conformation, the interval of $I_{855}/I_{831}$ ratio is between 0.3 and 1.5. And this ratio ranges from 1.7 to 2.5 for the “buried”
conformation. In our study, the corresponding statistical analyses (two independent sample t tests, SPSS 17.0, SPSS Inc) show that the $I_{555}/I_{831}$ ratio of NRT is 2.44 ± 0.05 and that of RTT is 1.39 ± 0.08. This proves that in NRT, most of the tyrosine residue in proteins are “buried,” which is good for keeping the stability of protein space structure. While for RTT, this conformation turns into “exposure.” This indicates that some of the –OH bands had combined with –COOH bands, which makes the tyrosine have a tendency to become “exposure” in the RTT compared with NRT.

5 Conclusion
Confocal micro-Raman spectroscopy provides important biochemical information because each molecule has its own vibration pattern that can be served as a “Raman biomarker.” Furthermore, these vibrations are usually sensitive to the structure of the molecular environment and can therefore reflect structural change. Our results confirm that Renal tumors can be characterized by a higher content of $\text{PO}_4^{2-}$. The Raman peaks at 788 and 1087 cm$^{-1}$ are used to test the content of $\text{PO}_4^{2-}$ in the RTT, and results show an obvious increase of Raman intensity. In addition, compared with NRT, tyrosine residue conformation in RTT turned from “buried” to “exposure”. The $I_{555}/I_{831}$ ratio is used as a maker of conformation variation. In this study, this ratio turned from 2.44 ± 0.05 in NRT to 1.39 ± 0.08 in RTT, which indicates more “exposure” tyrosine in the RTT than NRT. Also, confocal micro-Raman spectroscopy can be regarded as a new tool to detect renal tumors. We use PCA to test the ability of confocal micro-Raman spectroscopy to distinguish the RTT and NRT. The analysis result shows a good classification, which indicates the feasibility of confocal micro-Raman spectroscopy to provide a better understanding on molecule variations in renal tumor.
