Intrapulpal temperature changes during root surface irradiation with dual-wavelength laser (2780 and 940 nm): in vitro study

Rene Franzen, Borna Rashidisangsary, Seda Ozturan, Leon Vanweersch, and Norbert Gutknecht*

Abstract. The present study evaluated the intrapulpal thermal changes that occurred during the treatment of the root surfaces with a laser system emitting Er,Cr:YSGG 2780- and 940-nm diode laser irradiation in an alternating sequence. Thirty single-rooted human teeth were collected. The teeth were divided into three groups (n = 10 each) and irradiated with Er,Cr:YSGG alone or combined with a 940-nm diode laser. To investigate the intrapulpal temperature changes, specimens were embedded in a resin block with a set of thermocouples introduced at different positions within the root canals. The first group was irradiated with only Er,Cr:YSGG (25 mJ, 50 Hz, 50 μs pulse duration, water and air spray); the second group was irradiated with Er,Cr:YSGG (same setting) and a 940-nm diode (2 W, chopped mode with 20% duty cycle); the third group was irradiated with Er,Cr:YSGG (same setting) and a diode (2 W, chopped mode with 50% duty cycle). During all irradiations, thermal changes were recorded in real time with thermocouples. While group 3 showed thermal rises on average of 5.6°C in the pulp chamber, groups 1 and 2 showed average temperature rises of <0.5°C. The combined laser emission of 2780 and 940 nm is a promising way for root surface debridement without inducing intrapulpal thermal damage when using an appropriate water/air spray. All measured temperatures were considerably below the critical value of 5.6°C.

Keywords: Er,Cr:YSGG; diode laser 940 nm; dual wavelength; thermal analysis; debridement; scaling and root planing.

1 Introduction

Mechanical modification and debridement of the root surface is considered the gold standard of nonsurgical periodontal treatment for periodontally diseased teeth, which is accomplished through manual or ultrasonic instruments so as to remove bacterial biofilms, calculus, and deposits supraand subgingivally.1,4,6

However, this goal is not completely achieved since access to areas like furcations, concavities, grooves, and distal sites is limited; therefore, bacterial toxins, biofilms, and plaques may be left over the root surfaces, which consequently impair the predictable healing result and cause reinfection.6,10 Many different root modification methods have been applied to improve and stimulate the regeneration of periodontal ligament fibers on root surfaces. These include chemical, mechanical, growth factors, and different lasers.1–4,6,8

Lasers are one of the most promising new advancements for nonsurgical periodontal treatment due to tissue modification, detoxification, and bactericidal effects. Due to transmission and scattering effects, laser light may reach the areas, as mentioned above, where conventional instruments cannot.10,11

Scaling with erbium lasers has demonstrated comparable12–15 and even better outcomes than conventional scaling in that laser scaling not only removes calculus, plaques, reduces bacterial numbers, and has a positive effect in reduction of bacterial endotoxins, but also removes biofilms and provides a stable rough surface for better attachment of fibroblasts, blood clot, and periodontal ligament fibers.10,16–20

Dental calculus comprise CO3-substituted apatite crystals, water, and some other crystalline forms of phosphate and calcium; due to high absorptions of erbium laser in water and hydroxyapatite, erbium lasers have positive effects on the obliteration of mineralized bacterial plaques.18

Nevertheless, to remove hard tissue deposits and calculus, more intensity is needed; therefore, some side effects like overheating, microcracks, pit, grooves, and craters over the root surfaces have been reported.10

Any thermal changes of >5.6°C within the pulp cavity can lead to tooth necrosis if the temperature persists for too long, which must be avoided.21 As such, in the literature, minimal thermal changes on root surface, in pulp, bone, and adjacent tissues via utilization of erbium laser have been reported.10,22–25

Temperature elevation depends on time of exposure and, in consequence, on the total energy applied; the higher the power and the longer the treatment duration, the higher are the temperatures expected. Naturally, severe damages and altered root surfaces are expected when inappropriate laser parameters are utilized in either in vitro or in vivo situations.26–29

Therefore, the purpose of the present study is to examine the thermal changes in the pulp of extracted human teeth by simultaneous application (dual wavelength) of Er,Cr:YSGG and 940-nm diode lasers using a thermal bath and thermocouples in vitro,

compare the measured values with the critical threshold of 5.6°C and to critically discuss the applied parameters. Null hypothesis \( H_0 \): applications of combined 2.78- and 0.94-μm laser radiation increase the temperature in pulp cavity beyond critical point of 5.6°C.\(^{21}\)

Alternative hypothesis \( H_1 \): application of combined 2.78- and 0.94-μm laser radiation is safe for pulp in root debridement within the use of the investigated parameters.

2 Materials and Methods

For this cross-sectional laboratory study, three groups, consisting of 10 extracted human teeth per group, were examined. All samples \((n = 30)\) were single-rooted maxillary and mandibular teeth, which were free of caries, gross cracks, and restorations on root surfaces.

The teeth were always kept in a water-based solution with 0.1% thymol and 0.9% NaCl to prevent drying and bacterial growth. For temperature measurements, the teeth were prepared to be fitted with thermocouples (K-Type, model OMEGA, 5TC-TT-36, 0.13 mm diameter). Therefore, the root canals were prepared and enlarged with K-files up to ISO 40. To simulate a physiological situation, an artificial periodontal pocket model was manufactured by using cold-curing two-component polyurethane cast resin (ISO-PUR K 760), which was chosen because of its thermal conductivity being similar to cortical bone (0.58 W/Km) when mixed in a ratio of 5:1, resin:hardener (0.6 W/Km) as described by Hmud et al.\(^{20}\) Before pouring the resin, the whole tooth, except for the lowest 3 mm of the apical root, was wrapped in Teflon tape (12 mm × 0.1 mm × 12 mm) 10 times to shape a periodontal pocket of 1 mm width and at least 6 mm of depth around the teeth. Then, three thermocouples per tooth were placed at the cervical, middle, and apical third of each root canal; the access cavity was sealed with sticky wax; the locations of the three thermocouples’ ends were confirmed with a radiograph. The ends of the thermocouples were dipped into thermal compound (ARCTIC, MX-2) before insertion into the specimens to ensure optimal heat transfer from the dentin to the thermocouples. An exemplary specimen radiograph is shown in Fig. 1.

The other ends of respective thermocouples were connected to a digital thermometer (OM-USB-TC, OMEGA ENGINEERING, INC, USA), which is, in turn, connected to a computer to record the temperature in real time. To provide an environment with similar temperatures as the human oral cavity, a thermally stabilized water bath (GFL, waterbath type 1086, Germany) was used to host the specimens for the experiments. All laser irradiation procedures were done by the same person.

### 3 Laser Parameters and Protocols

For the three groups, the following parameters and protocols were used (Table 1).

The laser setup for the first group was Er, Cr:YSGG 2780 nm (serving as a control group) without any adjunct diode laser irradiation; the second one was Er, Cr:YSGG whose pulses were alternated with pulses of the 940-nm diode laser operating in chopped (gated) mode with a duty cycle of 0.2 (pulse duration to pulse period ratio of 20%), and the third group was Er, Cr: YSGG alternating pulses of the 940-nm diode laser with a duty cycle of 0.5.

For the Er, Cr:YSGG 2780 nm, the pulse energy was 25 mJ with a pulse repetition rate of 50 Hz and pulse duration of 50 μs (designated as H-mode by the manufacturer). For the 940-nm diode laser, all groups utilized a peak power of 2 W, with average powers resulting from multiplication with the respective duty cycle. In group 2, this yielded 0.4 W and in group 3, 1.6 W.

Note: W/A is the water air ratio. Delay is the delay time after the Er, Cr:YSGG pulse to start the diode pulse. Duration is the pulse duration of the laser. Pulse period is 1/repetition rate. The repetition rate is the same (50 Hz) for both lasers, as the diode laser emits exactly between the erbium laser emissions.
W. Radial firing periodontal tips (RFPT 5, BIOLASE, 6201176, LOT NO: 12.04.19) with a diameter of 500 μm and length of 14 mm were utilized. The alternating pulses emitted through the same laser tip are illustrated in Fig. 2 (here an exemplary duty cycle of 0.5 is shown for illustration, as is used in group 3). Individual pulse durations are listed in Table 1.

The water/air spray was set as water 80% and air 10% as a pilot study had shown the least temperature increases with this setting.

As seen in Table 1, samples in the first group were only irradiated by the Er,Cr:YSGG laser without any diode laser pulses, while specimens in the second and third groups were lasered with both Er,Cr:YSGG and alternating diode laser pulses. The whole irradiation time for each tooth specimen, with a pocket depth of 6 mm from the cementum-enamel-junction, was 60 s, including 30 s for the buccal pocket and 30 s for the lingual pocket side. To be exact, each 2 mm depth of pocket, at the labial and/or lingual root surface, was irradiated for 10 s. The laser fiber tip was held parallel to the long axis of the tooth and was moved in a scanning motion as in the standard clinical protocol with just one wavelength.

All irradiations were performed with the resin pocket-model inserted into a thermally stabilized water bath (GFL, waterbath type 1086, Germany) set to a temperature of 37°C. The actually measured temperature just outside the model was subtracted from the measured values at the intrapulpal thermocouples. These temperature rises above the baseline are called delta T (ΔT) hereinafter. Following each irradiation, 7 min were allowed for the specimens to return to the baseline temperature of the water bath.

In order to compare the groups statistically regarding the temperature rises at the apical, middle, and cervical positions of the thermocouples, a two-tailed paired t-test was performed in Microsoft Excel (version 14.2.4) and the p value was obtained (p < 0.01 was considered as significant, confidence level 99%).

4 Results

The mean values for the highest temperature rises were 1.68°C with a standard deviation of 0.98°C in group 3. Lower temperature increases were measured in groups 1 and 2, with 0.33 ± 0.04°C and 0.5 ± 0.19°C, respectively. The highest temperature increase was found in one specimen in group 3, in the apical third (specimen #10) with 3.81°C.

The maximum, mean, and standard deviation of maximum temperature changes (ΔT_max) for laser groups (groups 1, 2, and 3) in cervical, middle, and apical thirds of root canals have been described in Centigrade in Table 2. Tables 3–5 list the results of the groups in detail.

In groups 1 and 2, there was no significant difference between the means of delta temperature maximum of these

Note: S, sample. Final mean value and final standard deviation (over all specimen in that group) are in bold.
two groups at all, suggesting that the proposed settings do cause almost the same temperature rises in the apical, middle, and cervical regions of the tooth. Hence, intermitted 20% diode laser radiation with a peak power of 2 W does not significantly elevate the temperature in any tested area of the anterior teeth.

In the comparison of groups 1 and 2 with group 3, there was a significant difference between the means of delta temperature maximum of apical and middle thirds ($p < 0.01$), but no significant differences were observed on the cervical thirds of the above-mentioned groups.

### 5 Discussion

The most important criterion that one should consider in nonsurgical periodontal therapy is to have a clean root surface, which clinically means a root surface without bacterial calculus deposits, biofilm, and smear layer. In this condition, it would be a favorable place for gingival fibroblast attachment, which is considered the critical point for periodontal regeneration, in order to assure a new healthy connective tissue attachment.1

A myriad of instruments have been proposed for scaling and root planing, including lasers, especially in the erbium laser family (YAG and YSGG host crystals), that have shown promising results in periodontal treatment and fibroblast adhesion. Additionally, Er:YAG and Er:Cr:YSGG lasers have different morphological changes on the root surface compared to chemical means.1,10,12,31

In the present study, it was demonstrated that the accompanying use of a diode laser emitting at 940 nm alternating with Er:Cr:YSGG laser radiation was applied. Although temperature changes in group 3 showed a significantly higher difference ($p < 0.01$) from the other laser groups—only in middle and apical third of specimens—all temperature measurements were lower than the critical physiological limit of 5.6°C, i.e., these statistical significant differences were not clinically relevant. Mean $\Delta T_{\text{max}}$ in the cervical thirds does not show any significant differences ($p < 0.01$) among laser groups, which could be explained with the sufficient presence of water spray in the cervical thirds rather than the mesial and apical thirds.

Articles are mostly concerned with the morphological and thermal changes of root surfaces following the laser applications, while there are only few articles regarding temperature measurements within the pulp cavity when using erbium and diode laser irradiation (Table 6). To the best of our knowledge, this is the first study to report on the thermal effects of a dual-wavelength laser (2.78 μm and 940 nm) within the pulp cavity.

Theodoro et al.37 compared the morphological and thermal effects of Er:YAG and a diode of 810 nm on scaled and root-planed single-rooted teeth. No significant morphological alterations like melting, fusion, charring, or carbonizations were observed on SEM pictures, although root surfaces were more irregular in the Er:YAG laser group. A diode laser with an average power of 1 W and 1.4 W cw for 30 s caused a thermal increase of 1.6 and 3.3°C, respectively, while a temperature decrease of 2.2°C was recorded for the Er:YAG laser group.

In our study, a 940-nm diode laser emitting at 2 W in the chopped mode in the second and third groups with duty cycles of 20 and 50% was applied, respectively, yielding an average power of 0.4 and 1 W. Thus, temperature increase in the third group of the our study (1.68 ± 0.98°C) was very similar
to the findings of Theodoro et al.'s study (1.6 ± 0.8°C), although the time of irradiation in the presented study was 60 s, two times more than Theodoro et al.'s study, which can be explained by the presence of the water spray and the use of a stabilized thermobath, creating a more realistic model for the periodontal system.

Aoki et al. reported a temperature rise of 1.4°C during Er:YAG laser scaling under a water coolant. They also mentioned that the laser caused superficial microroughness over the root surface under SEM analysis.

Kreisler et al. investigated an 810-nm diode laser and recommended that a power output of 0.5 W for 10 s would be suited for lower incisors and upper first premolars, while a power of 1 W, also for 10 s, is the maximum output for other teeth; otherwise, by using more power, the pulp vitality may be jeopardized. Due to presence of water/air spray in our study, the time of irradiation could be increased to 60 s per tooth, without any adverse effects on temperature elevation in the pulp chamber. The maximum temperature rise, which was recorded for the third group, was 3.81°C, which is < 4°C, while the maximum temperature change was only 1.18°C in our study; the maximum temperature elevation in their study was 5.6°C according to Zach and Cohen.

Hmud et al. assessed the temperature elevation on the external root surface with a 940-nm diode laser while irradiating within the canal for 5 s to generate shock waves in water to disrupt the biofilm in endodontic treatment. They utilized 4 W peak power and 10 Hz, with an average power of 0.4 W; similar to group 2 of our study; the maximum temperature elevation in their study was 4°C, while the maximum temperature change was only 1.18°C in our study, which also emphasizes the positive effect of water/air spray in controlling the temperature. Indeed, the importance of a correct setting for the water/air spray is to be emphasized at this point. While our parameters have shown no significant temperature increase above any critical physiological limit, preliminary experiments before our study showed that with otherwise identical irradiation parameters, insufficient water to air ratios can lead to higher temperatures of up to 5.99°C in our case with a spray with a ratio setting of water 60% to air 30%.

### 6 Conclusion

Within the scope of this study, it can be concluded that Er,Cr:YSGG laser with a pulse energy of 25 mJ, 50 Hz, 80% water, 10% air spray is safe as an adjunct periodontal therapy to root-plate while removing the biofilm covering the root surface; additionally, since a diode laser is used in between erbium laser pulses, disinfection and bactericidal effects can be applied without any thermal damage to the pulp vitality. This new combination therapy concept might be a promising approach in periodontology. The proper portion of water/air spray plays a crucial role in controlling the temperature changes within the pulp during a laser-based scaling and root debridement.

The alternative hypothesis (H₁) formulated beforehand can be confirmed: the application of the dual wavelength is safe for pulp in root debridement; while the null hypothesis (H₀) is rejected.

The application of this dual-wavelength laser under the mentioned parameters does not increase the temperature in the pulp cavity beyond the critical point of 5.6°C according to Zach and Cohen.
