Design considerations for $\lambda \sim 3.0$- to 3.5-$\mu$m-emitting quantum cascade lasers on metamorphic buffer layers

Ayushi Rajeev, Christopher Sigler, Tom Earles, Yuri V. Flores, Luke J. Mawst, and Dan Botz

Abstract. Quantum cascade lasers (QCLs) that employ metamorphic buffer layers as substrates of variable lattice constant have been designed for emission in the 3.0- to 3.5-$\mu$m wavelength range. Theoretical analysis of the active-region (AR) energy band structure, while using an 8-band $k\cdot p$ model, reveals that one can achieve both effective carrier-leakage suppression as well as fast carrier extraction in QCL structures of relatively low strain. Significantly lower indium-content quantum wells (QWs) can be employed for the AR compared to QWs employed for conventional short-wavelength QCL structures grown on InP, which, in turn, is expected to eliminate carrier leakage to indirect-gap valleys ($X$, $L$). An analysis of thermo-optical characteristics for the complete device design indicates that high-Al-content AlInAs cladding layers are more effective for both optical confinement and thermal dissipation than InGaP cladding layers. An electroluminescence-spectrum full-width half-maximum linewidth of 54.6 meV is estimated from interface roughness scattering and, by considering both inelastic and elastic scattering, the threshold-current density for 3.39-$\mu$m-emitting, 3-mm-long back-face-coated QCLs is projected to be 1.40 $\text{kA/cm}^2$. © The Authors. Keywords: quantum cascade laser; metamorphic buffer layer; semiconductor laser; metalorganic chemical vapor deposition.

1 Introduction

High-power lasers operating in the mid-infrared (IR) spectral region with emission in the 3.0- to 3.5-$\mu$m wavelength range have garnered interest due to applications such as advanced remote sensing and ranging. High-performance, low threshold-current density, interband-transition lasers have been reported within the 3.0- to 3.5-$\mu$m wavelength range by employing either type-I quantum wells (QWs) or type-II QWs (i.e., interband cascade lasers). However, such devices are highly temperature sensitive due to hole leakage (in the case of type-I QW devices) as well as Auger recombination and/or Auger-assisted carrier leakage. As a result, such devices exhibit low threshold-current characteristic temperature coefficients, $T_0$, and low slope-efficiency characteristic temperature coefficients, $T_1$. Since the maximum CW power, $P_{\text{max}}$, is a strong function of $T_0$ and especially $T_1$ values, this explains why the $P_{\text{max}}$ values have been relatively low (<500 mW) from both type-I and type-II QW lasers operating in this wavelength range.

Quantum cascade lasers (QCLs), being intersubband (ISB)-transition devices, do not suffer from Auger recombination, thus relatively high $T_0$ values can be obtained and have achieved a wide range of emission wavelengths using a single-material system for designing and fabricating devices. However, when using conventional substrates, such as InP and GaAs, the materials constituting the superlattice (SL) core region of the QCL are constrained by strain-induced critical-thickness limitations. It is well known that the degree of strain relaxation induced increases as one approaches the critical thickness of the individual (compressive-strained) QW and (tensile-strained) barrier layers constituting the SL, thus leading to subsequent device failure. Strain relaxation can also develop if the average strain of the SL core region becomes too large. However, the actual strain limits that can be tolerated without relaxation are impacted by kinetic factors, which, in turn, depend on the growth temperature and growth rate.

The imposed strain limitations are in direct conflict with one of the foremost requirements for QCLs in the 3.0- to 3.5-$\mu$m wavelength regime, which is to have large conduction-band (CB) offsets between wells and barriers in order to accommodate the high transition energies. Even if strain relaxation is not present, high strain affects the interface morphology in the active regions (ARs) of the stages of the QCL core region, which, in turn, is expected to impact the device performance. InP-based 3.56-$\mu$m-emitting QCLs have demonstrated high CW output power (0.5 W), although such devices utilize InGaAs/AlInAs-SL ARs of highly strained ($\Delta a/a \sim 2\%$) QWs and barriers. While relatively high $T_0$ values (152 to 166 K) were obtained, the $T_1$ value was moderately high (~190 K) only for 3.56-$\mu$m-emitting devices, as it dropped to ~116 K for 3.39-$\mu$m-emitting devices, most likely due to the onset of leakage to satellite valleys. Similarly, 3.3-$\mu$m-emitting devices have displayed low $T_1$ values (~71 K), over the 250- to 300-K temperature range, indicating strong carrier leakage to satellite valleys. The $T_0$ values were also found to be low (100 K) above an operating temperature of 250 K, due to carrier leakage and possibly strong backfilling, considering the relatively high injector-doping level. Even higher strain ($\Delta a/a \sim 3\%$) barriers have been used to enable the emission wavelength to be as short as 3.0 $\mu$m, although very low $T_0$ and $T_1$ values limited the CW output power to quite low...
values (∼2.5 mW). Such poor performance was most likely due to strong carrier leakage to satellite valleys (L, X) for ∼3.05-μm-emitting devices grown on InP.

We have previously proposed the use of metamorphic buffer layers (MBLs) as the means to achieve high-performance low-strain QCLs at 3.0- to 3.5-μm emission wavelengths. These “virtual substrates” under consideration were grown on (001) GaAs substrates by hydride vapor phase epitaxy. They consisted of nine In$_x$Ga$_{1-x}$As layers with linear grading of the In content in each of the nine ∼10-μm-thick steps. The final layer was a constant-composition cap layer which is typically ∼15-μm thick to allow for surface preparation in order to perform the regrowth of strained layers atop with high fidelity. The MBL cap is found to be nearly fully relaxed (>95%), owing to its thickness, and exhibits tilt with respect to the substrate, which is a function of composition and thickness. The MBL enables trapping of misfit dislocations at the composition steps while forcing the threading dislocations to glide to the edges of the sample, thus giving us a virtual substrate with a threading-dislocation density of the order of ∼10$^2$ cm$^{-2}$. However, the induced strain relaxation in the MBL results in a cross-hatched surface morphology which is detrimental to QCL-device performance. The use of chemical–mechanical planarization (CMP) with appropriate applied pressure on the MBL cap was found to reduce the cross-hatching height by more than 20 times. A single stage of the QCL structure grown atop an MBL, which had undergone the CMP treatment, did result in electroluminescence (EL) emission near 3.6-μm wavelength from mesa devices tested at 80 K. However, indium enrichment was observed in the MBL cap layer when heated to high-regrowth temperatures. An additional wet-chemical etching step introduced after the CMP resolved this issue and provided an eti-appropriate surface for regrowth of strained SL layers.

Ten stages of the QCL structure of the AR design for 3.4-μm emission target wavelength were grown with high fidelity on an MBL using the aforementioned optimized surface treatment, as confirmed by x-ray diffraction and transmission electron microscopy. To enable growth of the complete laser design, several challenges remain such as the choice of cladding material and optical-waveguide design, which are being addressed in this study. Moreover, the structural, thermal, and optical characteristics of the ternary cladding material, with specific compositions that are lattice-matched to the MBL, have not been previously reported.

A direct consequence of using MBLs is the expansion of the design space for QCLs emitting at mid-IR wavelengths by having an application-oriented custom-grown substrate. Here, we perform a comprehensive design optimization of a particular AR design based on an MBL employing an In$_{0.22}$Ga$_{0.78}$As cap layer. A thermo-optical analysis for the complete laser design indicates that the use of In$_{x}$Al$_{1-x}$As cladding layers allows for both good optical confinement and adequate heat transport.

2 Quantum Cascade Laser Design

2.1 Quantum Cascade Laser Active-Region Design

To analyze the design of the QCL ARs grown on MBLs, the energy-band structure, electronic wavefunctions, and electron energy-state lifetimes have been calculated using an 8-band k$\cdot$p code, as previously reported. Conventional QCL structures utilize fixed compositions for the wells and barriers with variations only in the thickness of each layer type. For such QCLs, it has been found that for 3.76-μm-emitting devices one can achieve both efficient carrier-leakage suppression and fast, miniband-like carrier extraction when using, for lower-laser-level depopulation, the single-phonon-resonance (SPR) AR structure in conjunction with resonant-tunneling extraction from the lower laser level. We have achieved the same type of AR design (i.e., SPR + miniband extraction) for our short-wavelength (λ = 3.0 to 3.5 μm) QCL structures grown on MBLs. More specifically, an SPR + miniband extraction AR design was reached given a lattice constant of 0.574 nm for the virtual substrate (i.e., the cap layer of the MBL) so as to provide a relatively low-strain QCL structure for emission in the 3.0- to 3.5-μm wavelength range. Such a design, based on an MBL cap composition of In$_{0.22}$Ga$_{0.78}$As, with a 10-stage core region consisting of AlAs barriers and In$_{0.45}$Ga$_{0.55}$As wells, and designed to emit at 3.39 μm has been grown by using metalorganic chemical vapor deposition (MOCVD) of high crystalline quality.

The layers thicknesses (expressed in Å) within one stage of the QCL core region are as follows: 25/16/24/17/21/18/20/21/19/21/18/17/28/12/13/39/10/33/16. The bold-faced layers are the wells and the other layers are barriers, with the doped layers (n-type, 2 × 10$^{17}$ cm$^{-3}$) indicated by italics. Figure 1 shows the CB diagram and relevant electronic wavefunctions for this design at the indicated applied electric field.

2.2 Complete Quantum Cascade Laser Structure: Thermo-Optical Analysis

The AR modeling is followed by the 1-D optical analysis of the complete laser structure shown in Fig. 1. This makes use of a wave-transfer matrix method for TM-polarized light. Using the refractive-index profile of this structure (Table 1), the wave-transfer matrix method is employed to analyze the optical confinement and mode profiles obtained. We consider two different cladding materials, In$_x$Al$_{1-x}$As and In$_{0.45}$Ga$_{0.55}$As, with both materials being lattice matched to the MBL and have refractive indices lower than the average refractive index of the SL core region.
As the MBL cap is ∼10-μm thick and nearly fully relaxed, for all simulations, the constant composition in the cap (i.e., In₀₂₁Ga₀₇₉As) is treated as a substrate. The upper and lower-cladding layers are grown lattice matched to the MBL cap and consist of either In₀₂₁Al₀₇₉As or In₀₆₉Ga₀₃₁P. The upper and lower optical-confinement layers are In₀₂₂Ga₀₇₈As. The QCL core region comprises 30-stages, with the layer thicknesses and doping levels for a stage described above. The last semiconductor layer grown is a highly n-type-doped contact/plasmon layer, which is In₀₂₁Al₀₇₉As or In₀₆₉Ga₀₃₁P. An additional thin, highly doped In₀₂₂Ga₀₇₈As contact layer could be grown on top to provide a low-resistance ohmic contact, although this is not included in the model for simplicity. This is followed by Ti/Au metal contact layers.

The Drude model is employed to determine the refractive indices of each of these layers for an emission wavelength of 3.4 μm. Specifically, for the core region, the refractive index is obtained by averaging over 30 stages of alternating well and barrier layers and also taking into account the injector layers that are intentionally doped. Refractive indices for the metal layers are obtained from Refs. 22 and 27.

The thermal analysis for the structure is conducted using the heat transfer module of the COMSOL Multiphysics software package. Steady-state equations are employed for analyzing the thermal dissipation under CW operation of the QCL. The QCL is considered to be processed to form ridge waveguides 10-μm wide. A two-step gold electroplating process will then be employed to fill in the trenches and obtain a planar top surface for mounting. The chip will be mounted in epi-down fashion using 4-μm-thick indium solder on a 300-μm-thick diamond submount already bonded to a copper heatsink, which will be 1.5-mm thick and 3-cm wide. The boundary conditions for the packaged chip are set as room temperature for the bottom of the heatsink, with the other boundaries being adiabatic.

The thermal conductivities are listed for all the materials involved in fabricating and packaging this laser, providing the temperature dependences where known (Table 2). The challenge, as stated earlier, is to estimate the appropriate value of thermal conductivities for the two cladding-layer options for this QCL design: In₀₂₁Al₀₇₉As and In₀₆₉Ga₀₃₁P. The dependence of thermal resistivity of a ternary alloy on the binary-compound resistivities is as follows:

\[ T_{A,B->C}(x) = xB_{AC} + (1-x)B_{BC} + C_{A-B}(1-x), \]  

where \( C_{A-B} \) is the bowing parameter owing to the lattice disorder originating from the random distribution of A and B atoms on the interchangeuable sublattice sites. C_{In-Ga} has been calculated to be 72 W⁻¹ cm⁻¹ deg cm at room temperature from fitting the thermal resistivity data of InAs-GaAs alloys and is assumed to be the same for InP-GaP alloys. This bowing parameter results in thermal resistivities that are in good agreement with those experimentally determined for InₓGa₁₋ₓP layers of different x concentration.

The disorder alloy-bowthing parameter for InAlAs is estimated to be 60 W⁻¹ deg cm⁻¹. These are yet to be confirmed experimentally. The thermal resistivities for the binary alloys under consideration, namely InAs, AlAs, InP and GaP, have all been well characterized.

The anisotropic thermal conductivity for the core region is assumed to be close to that obtained for a conventional 4.6-μm-emitting QCL. This is expected to suffice for the purpose of comparing the effectiveness of using InAlAs versus InGaP as cladding-layer materials.

3 Results and Discussion

Key parameters used in determining the device performance, for the 3.39-μm-emitting AR design shown in Fig. 1, are listed in Table 1. For this optimized AR design, resonant-tunneling extraction (to the next injector region) occurs from both the lower laser level (state 2) and the state below it (state 1), which constitutes miniband-like extraction. In turn, as evident from Table 1, the lower-laser-level global lifetime $\tau_{32g}$ (0.195 ps) is basically half the value of the lower laser level and lower laser level, $\tau_{32g}$ (0.397 ps). As a result, the room-temperature slope efficiency is expected to be significantly higher, due to both higher laser-transition differential efficiency and, as discussed below, less carrier leakage, just as in the case of SPR + miniband extraction, 3.76-μm-emitting QCL versus SPR-only, 3.56-μm-emitting QCLs. The upper-laser-level global lifetime $\tau_{3g}$ requires a delicate balance of maximizing its value (often easily obtained by having extended wavefunctions throughout the AR and beyond) with the opposing need for a highly vertical laser transition. Keeping the ratio of upper laser levels’ lifetimes and lower laser levels’ lifetimes relatively large enables effective population inversion.

In structures with resonant extraction from the lower laser level both that level (state 2 in this case) and the extractor level (state 2') are considered for the lasing transition. Thus, the dipole matrix element is a global one, $\langle \zeta_{32g} \rangle$, taking into account transitions from both (energy) levels 3 to 2 and from levels 3 to 2', and signifies the degree of overlap between the corresponding wavefunctions. $\tau_{32g}$, the global lifetime for the laser transition, needs to be maximized such that the global, effective upper-lifetime converges to $\tau_{3g}$ as the lifetime ratio $\tau_{32g}/\tau_{32g}$ approaches zero.

The figure of merit (FOM) using these critical parameters, for a first-order approximation of the threshold-current density, $J_{th}$, is as follows:

$$FOM = |\zeta_{32g}|^2 \left\{ \frac{\tau_{3g}}{\tau_{32g}} \right\}.$$  (2)

and since the backfilling current is negligible in both structures, due to very large values for the energy difference (at threshold) between the lower laser level, state 2, and the ground state, state g, in the next injector, $\Delta_{32g}$ (Table 1), one obtains

$$J_{th} \propto \frac{1}{FOM}.$$  (3)

The illustrated QCL design has an FOM value of 127.9 Å²ps compared to the calculated value of 181.3 Å²ps for the 3.56-μm QCL grown on InP. However, the FOM values do not take into account the carrier leakage from the upper laser level, which, as discussed below, is significantly lower for our 3.39-μm QCL design on MBL than for the 3.56-μm-emitting QCL design on InP. Thus, the actual difference between the achievable $J_{th}$ values for the two devices will definitely be lower than indicated by the calculated FOM values.

The relative low value for the energy difference between the upper laser level, state 3, and the next higher AR energy state, state 4, $E_{43}$, of the 3.39-μm QCL on MBL (i.e., 84.4 meV) will result in negligible carrier leakage through thermal excitation from state 3 to state 4 and consequent relaxation to the lower AR energy states (i.e., to 1, 1', 2, and 2'). This will happen because the $E_{43}$ value strongly impacts the scattering rate from state 3 to state 4 (1/τ₄₃) and, in turn, the leakage-current density $J_{leak}$. The former is estimated as follows, given an electronic temperature $T_{e3}$ in state 3:

$$\frac{1}{\tau_{43}} \approx \frac{1}{\tau_{43}} \exp \left( -\frac{E_{43}}{kT_{e3}} \right).$$  (4)

To reduce the scattering rate into the upper AR energy states (i.e., 1/τ₄₃), we designed QCLs with large $E_{43}$ and $r_{43}$ values. The resulting design characteristics, related to the device performance, are reduced temperature sensitivities for the threshold-current density, $J_{th}$, and the slope efficiency, $\eta$, (i.e., higher $T_{0}$ and $T_{1}$ values) and subsequently increased maximum CW power, $P_{max}$, and maximum CW wallplug efficiency, $\eta_{wp, max}$, due to higher values for $T_{0}$ and especially higher values for $T_{1}$. From Table 1 one can see that

Table 3: Key parameters for SPR + miniband extraction QCL-structure designs grown on an MBL: the operating field at threshold; the energy difference between the upper laser level, state 3, and the next higher AR energy state, state 4, $E_{43}$; the energy level separation between the lower laser states (states 2 and 2') and the ground state of the next-stage injector, $\Delta_{g}$; the dipole matrix element between the upper laser level and lower laser level, $\zeta_{32g}$; the lifetime of transitions between state 4 and state 3, $\tau_{3g}$, the global lifetimes for the upper and lower laser states, $\tau_{3g}$ and $\tau_{2g}$; the average strain per stage; and the strain of well and barrier layers. For comparison, we also show the same parameters for SPR-only QCLs on InP.

while the $\tau_{43}$ values are similar for the two compared devices, the $E_{43}$ value is higher for 3.39-$\mu$m QCLs on MBL than for 3.56-$\mu$m QCLs on InP (i.e., 84.4 meV versus 65.1 meV). This is consistent with the fact that the $E_{43}$ value generally decreases with increasing field strength; thus, given that the 3.56-$\mu$m QCLs on InP has a significantly higher field strength than our 3.39-$\mu$m device on MBL (i.e., 194 versus 142 kV/cm), the higher $E_{43}$ value for the device grown on MBL is justified. Since, as seen from Eq. 5, the scattering rate to the upper AR states is an exponential function of $-E_{43}$, the carrier leakage will be significantly lower for 3.39-$\mu$m QCLs on MBL than for 3.56-$\mu$m QCLs on InP. We note that for these 3.4-$\mu$m-emitting QCLs on MBL we have been able to achieve both carrier-leakage suppression as well as miniband-like extraction without the need for deep QWs in the AR or tapered barrier heights in the AR. In addition, carrier leakage to satellite valleys (L, X) is also substantially reduced owing to the lower In percentage in QW (i.e., 45%) for this QCL on MBL when compared to conventional QCLs grown on InP substrates for the wavelength range being studied (e.g., 80% for 3.56-$\mu$m-emitting QCLs and 72% for 3.3-$\mu$m-emitting QCLs). As pointed out above in Sec. I, with increasing strain, which means with increasing In content in the QWs, such leakage becomes a significant portion of the total room-temperature $J_{th}$ value for devices grown on InP, unlike devices designed for emission in the 3.5- to 4.0-$\mu$m range.

Large $\Delta_{inj}$ values, like the ones in Table 3, ensure that the backfilling-current density due to thermal excitation from the ground state in the injector region of a stage to the lower laser level in the AR of the previous stage is minimized. However, a trade-off exists here as too large a value for $\Delta_{inj}$ will result in undesirably high voltages. Note that the QCL design on MBL presented in Table 3 has a significantly lower $\Delta_{inj}$ value compared to that for the QCL design on InP. This will result in a reduction in operating voltage, yet the $\Delta_{inj}$ value is large enough to minimize carrier backfilling, as further discussed below.

Other important characteristics for this design are a low average strain per stage (here: net compressive) and a fairly high temperature $\Delta_{inj}$/$\Delta_{inj}$ product for the wells and barriers in the AR. The significantly lower strain values for the MBL-based QCL designs, compared to those for conventional short-wavelength QCLs, alleviate the issues of strain relaxation and may ultimately lead to improved device reliability for 3.0- to 4.0-$\mu$m-emitting QCLs.

Optical-mode confinement analysis is performed by combining the designed core region with cladding and optical-confinement layers forming the complete laser structure. The refractive-index steps between the In$_{0.21}$Al$_{0.79}$As cladding layers and the core region are higher than when using In$_{0.66}$Ga$_{0.33}$P cladding layers. Straightaway, this gives superior optical-mode confinement to the core region when using InAlAs cladding layers. The threshold-current density is calculated as follows:

$$J_{th} = \frac{\alpha_m + \alpha_{cc,eff}}{\eta_{inj,\text{tot}} \Gamma g} = \frac{\alpha_m + \alpha_{cc,\text{sim}} + \alpha_{bb,\text{bf}}}{\eta_{inj} \eta_{bf} \Gamma g}$$

where $\alpha_m$ is the mirror loss, $\alpha_{cc,\text{sim}}$ is the simulated loss that includes free-carrier absorption losses and radiation leakage loss to the substrate owing to the antiguided nature of the transverse waveguide in the structure, $\alpha_{bb,\text{bf}}$ is the sum of ISB absorption losses in the injector regions and the equivalent loss corresponding to backfilling, $\eta_{inj,\text{tot}}$ is the total injection efficiency, $\eta_{inj}$ is the tunneling-injection efficiency into the upper laser level, $\eta_{bf}$ is the pumping efficiency which reflects the degree of carrier leakage (i.e., $\eta_{bf} = 1 - J_{\text{leak}}/J_{th}$), $\Gamma$ is the (transverse) optical-mode confinement factor to the core region, and $g$ is the differential gain in the case of unity tunneling-injection efficiency and no carrier leakage.

The loss term $\alpha_{bb,\text{bf}}$ can be considered to be negligible for these devices for the following reasons: (1) the ISB absorption, a measure of optical losses in the injector regions due to absorption between minibands, drops fast with emission wavelength (i.e., from $\sim 2.3$ cm$^{-1}$ at $\lambda = 8.8$ $\mu$m to $\sim 0.5$ cm$^{-1}$ at $\lambda = 4.6$ $\mu$m), since with increased CB offset the injector-region minibands are further apart energywise, thus, since for our case the CB offset is significantly larger than for 4.6-$\mu$m-emitting devices, the ISB absorption will become negligible; (2) the backfilling-current density, $J_{bf}$, will be negligible since the $\Delta_{inj}$ value is rather large (i.e., 226 meV) compared to values in the 120- to 150-meV range for 4.6-$\mu$m-emitting QCLs and given that $J_{bf} \propto \exp(-\Delta_{inj}/kT_{eq})$.

The device cavity length is taken to be 3 mm, and the reflectivities for the high-reflectivity (HR)-coated back facet and the uncoated front facet are taken to be 97% and 27%, respectively. The value for differential gain $g$ is calculated using the expression for gain cross-section $\sigma_g$ divided by $\Gamma$ and multiplied by $\tau_{up,\text{opt}}$ the global, effective upper-state lifetime.
\[ g = \tau_{up,g} \times \frac{4\pi e^2 \Lambda^2}{\varepsilon_0 n_{refr} \lambda^2 2 \gamma_{32} L_p}, \]  
\[ \tau_{up,g} = \tau_3 \left(1 - \frac{\tau_{32}}{\tau_3} \right), \]  
\[ 2\gamma_{32} \text{ is the full-width half maximum (FWHM) broadening of the transition, as obtained from EL measurements, } L_p \text{ is the thickness of one stage, } \lambda \text{ is the emission wavelength of the QCL, and } n_{refr} \text{ is the average refractive index for the AR as per the design.} \]

We use the 4.6-μm-emitting QCL by Lyakh et al. as the standard device for comparison to our design, as far as the value of the \( \eta_{inj, tot} g \) product, due to the similarity in crystal-growth method employed (i.e., MOCVD) for the core region.

First of all, for \( \eta_{inj, tot} \), we consider a typical \( \eta_{inj} \) value of 0.97, and for \( \eta_g \) we take 0.85, since those devices had strong carrier leakage as evidenced by a low \( T_1 \) value of 140 K which we have shown to correspond to \( \eta_p \approx 0.85 \) for conventional 4.6- to 4.7-μm-emitting QCLs. Then \( \eta_{inj, tot} = 0.82 \). Further confirmation that 0.82 is a good estimate for the \( \eta_{inj, tot} \) value is the relatively large discrepancy found by Maulini et al. between calculated and experimental wall-plug efficiency values [i.e., a factor of 0.77 that corresponds to ~0.80 for \( \eta_{inj, tot} \) when taking into account the small deviation from linearity (~4%) of the pulsed \( I - L \) curve at drives corresponding to the maximum wallplug efficiency].

As for \( g \), one can use the parameters provided in Ref. 44 with the exception of the \( \tau_{up,g} \) value for which the lifetimes provided in Ref. 45 take into account only longitudinal optical phonon scattering; that is, only inelastic scattering. Fortunately, the same structure was studied in Ref. 44 and good agreement with experiment was found when \( \tau_{40,elastic} = 1.1 \text{ ps} \) and \( \tau_{40,inelastic} = 1.5 \text{ ps} \). [The elastic part is primarily due to interface-roughness (IFR) scattering.] Then, the total global upper-state lifetime \( \tau_{40, tot} \) is 0.635 ps, that is, 1.73 times lower than \( \tau_{40,inelastic} \).

Thus, the value for the \( \eta_{inj, tot} g \) product calculated without considering elastic scattering: 14.7 cm/kA, reduces to a value of 6.97 cm/kA (when elastic scattering is considered).

We note that this estimated value is in excellent agreement with the experimental value of 6.8 cm/kA thus, it gives us confidence that applying the same procedure will provide a reasonably accurate value for the \( \eta_{inj, tot} g \) product, as needed in order to estimate the potential \( J_{th} \) values for 3.39-μm-emitting QCLs on MBLs.

The room-temperature \( J_{th} \) value for the 4.6-μm-emitting QCL was 1.5 kA/cm² for a 40-stage core-region device. We scaled it to 1.73 kA/cm² for direct comparison to 30-stage core-region devices. Moreover, when considering a 3-mm-long cavity with one HR-coated back facet, the \( J_{th} \) value becomes 1.28 kA/cm² (see Table 3). Having obtained good agreement between calculated \( J_{th} \) values and experimental results, the same estimation procedure is applied to the 3.39-μm-emitting QCL-on-MBL design.

An EL spectral linewidth, \( 2\gamma_{32} \), of ~50 meV is expected, that is, a similar value as for ~3.76-μm-emitting QCLs of similar QW and well strain (i.e., \( \sim \pm 1.5\% \)) and same lower-level depopulation scheme (i.e., SPR + miniband extraction). As a matter of fact, the EL linewidth in mid-IR QCLs is primarily due to IFR scattering and we calculate a value of \( 2\gamma_{32} \approx 54.6 \text{ meV} \) for the 3.39-μm-emitting QCL on MBL design. The calculated EL spectrum is shown in Fig. 3. The EL spectrum in this design will be primarily due to radiative transitions from level 3 into levels 2 and 1 (Fig. 4). Furthermore, because of the lower optical dipole matrix element for the 3 to 2 radiative transition compared to the 3 to 2 transition (4.5 versus 10.1 Å), the intensity of the 3 to 2 EL component is reduced by a factor of ~5.1. The FWHM values of the individual EL spectra correspond to the IFR-induced inhomogeneous broadening values between the involved levels and are calculated as in Refs. 48 and 49.

\[ \tau_{ISR, 3(2,2')} = \frac{\pi m_e}{\hbar^2} \Delta^2 \Lambda^2 \Delta \sum_i \Delta^2 \rho_i \left( z_i \right) \left( z_i \right), \]  
where \( m_e = 0.0472 m_0 \) is the CB effective mass in the In0.45Ga0.55As QW material, \( \Delta = 0.14 \text{ nm} \) is the in-depth roughness height and \( \Lambda = 6 \text{ nm} \) is the in-plane roughness correlation length, \( \Delta \rho_i = 1.2 \text{ eV} \) is the gamma-valley CB offset for the In0.45Ga0.55As/AInAs heterointerface, and \( \rho_i \left( z_i \right) \) are the wavefunction amplitudes of the involved levels at the \( i \)th interface. It is important to note that minimal adjustment of the roughness parameters (\( \Delta, \Lambda \)) was used with respect to values reported in the literature, as for example in...
Ref. [50]. Specifically, we use $\Delta = 0.14$ nm and $\Lambda = 6$ nm, whereas $\Delta = 0.15$ nm and $\Lambda = 6$ nm were used in Ref. [50]. In our consideration, such fluctuations in the roughness parameters are expected in the analysis of samples from different labs/growth sources. Altogether, we find excellent agreement between calculated (54.6 meV) and expected ($\pm 50$ meV) $2\gamma_{32g}$ values.

Table 5 summarizes calculated scattering times for IFR-induced ISB scattering between selected states of the 3.39-$\mu$m-emitting QCL on MBL design. These values are calculated as in Ref. [50].

$$
\frac{1}{\tau_{m,n}} = \frac{\hbar m_c}{\hbar^2} \Delta^3 \sum_{i} \Delta^2 E_{g0}^2(z_i) \omega_{g0}^2(z_i) \exp \left( -\frac{\Lambda^2 m_c E_{mn}}{2\hbar^2} \right),
$$

(9)

with $m = 3$ and $n = 2, 2', 1, 1'$ as in Fig. 4. $E_{mn}$ is the ISB energy spacing between individual levels. The same parameters as in Eq. (9) are used in the calculations of Eq. (9). We calculate a global IFR relaxation time for the upper laser level, state 3, of ~0.724 ps.

For $\eta_{int rej}$, we obtain a value of 0.94 using calculated values of 0.97 for both $\eta_{inj}$ and $\eta_{rej}$. The relatively high value for $\eta_{rej}$ is a reflection of both high $E_{23}$ (84.4 meV) and $\tau_{23}$ (0.51 ps) values, which lead to negligible leakage current [see Eq. (9)]. Using total values (i.e., including IFR scattering) for $\tau_{2p}, \tau_{22g}, \tau_{22g'}$, we obtain a total value for $\tau_{2p,2g}$ of 0.428 ps. Then, the gain coefficient $g$ is calculated to be 3.14 cm/kA and is kept constant along with the waveguide loss for all simulations following.

Asymmetry of transverse-field profiles (as seen in Fig. 4) is due to the unequal thicknesses of the optical-confinement layers employed in these designs (Fig. 4). These thicknesses are chosen in accordance with the optimization of the $I_g$ product and the sum of losses ($\alpha_{tot} = \alpha_m + \alpha_{w, sim} + \alpha_{sib,St}$) in order to obtain the lowest $J_{th}$ value. For a fixed lower-cladding thickness of 2 $\mu$m and upper-cladding thickness of 3.5 $\mu$m, the best-case scenarios with highest $\Gamma$, lowest $\alpha_{tot}$, and lowest $J_{th}$ values are shown in Fig. 5.

On observing that InAlAs is the material of choice over InGaP in order to obtain the lowest $J_{th}$ value for these QCLs (Table 6), the impact of varying the thickness of the lower-cladding layer is studied for 3-mm-long, HR-coated devices. It is evident that the 3-$\mu$m-thick InAlAs lower-cladding configuration is theoretically the best in terms of the confinement factor and loss coefficient $\alpha_{sib}$, and that the $J_{th}$ value is expected to be only ~10% higher than that for the 4.6-$\mu$m-emitting QCL. There is room for improvement by increasing the cavity length to 5 mm in order to reduce $\alpha_m$ and consequently, $J_{th}$. That is, for $L = 5$ mm, the $J_{th}$ value decreases to 0.99 kA/cm$^2$ for the 3-$\mu$m-thick InAlAs lower-cladding design. Additionally, this configuration results in a symmetric mode profile owing to equal lower and upper confinement layer thicknesses, again obtained by minimizing the $\alpha_{tot}/\Gamma$ quantity.

We also performed a thermal analysis that provides understanding of heat dissipation in 3.4-$\mu$m-emitting QCLs on MBL with InAlAs and InGaP cladding layers when compared to an InP-cladding 4.6-$\mu$m QCLS. InP is the obvious cladding-layer choice for InP-based QCLs being a well-characterized binary material with high thermal conductivity (68.03 W/m · K).

The thermal dissipation simulation is performed on a model using the best configuration obtained from optical-mode analysis for the 3.4-$\mu$m-emitting QCL using InAlAs cladding layers [Fig. 5(c)]. This is compared to QCL structures with InP and InGaP cladding layers as to analyze the effectiveness of these materials as thermally conducting cladding layers [Figs. 5(a) and 5(b)]. 10-$\mu$m-wide and 5-mm-long ridge structures are considered, with a Si$_3$N$_4$ current-confinement dielectric layer, and plated Au around and above the ridge.

**Table 6** Comparison of InGaP versus InAlAs as lower-cladding layers for 3.4-$\mu$m-emitting QCLs, and of 3.4-$\mu$m-emitting QCLs on MBL versus 4.6-$\mu$m-emitting QCL

To quantify this heat dissipation, we look at the average temperature rise, $\Delta T_{\text{act}}$, in the core region with respect to the heatsink temperature, which is taken to be room temperature. We assume 5% CW wallplug efficiency for the input power (i.e., 95% of the input power will be dissipated as heat). The 5% value is chosen to be about twice that obtained for 3.56-μm-emitting QCLs at room temperature (i.e., ~2.5%), since our structure has carrier-leakage suppression which has been shown to result in basically doubling of the CW wallplug efficiency value compared to devices with significant carrier leakage. The $\Delta T_{\text{act}}$ value for structures with InP, InGaP, and InAlAs claddings, given 15 W of input power, is 33.6, 74.6, and 63.8 K, respectively. That is, using InAlAs claddings increases $\Delta T_{\text{act}}$ by a factor of ~1.9 compared to when using InP claddings and decreases $\Delta T_{\text{act}}$ by ~15% to when using InGaP claddings. The former illustrates the expected penalty in thermal conduction for short-wavelength QCLs employing ternary-cladding layers lattice matched to the virtual-substrate layers atop MBLs.

4 Conclusions
A mid-IR QCL with an emission wavelength of 3.4 μm is designed for a virtual substrate of the composition In$_{0.22}$Ga$_{0.78}$As. This design has the advantage of depopulation of the lower laser level involving both the SPR scheme and resonant-tunneling extraction to the extractor/injector region. In turn, one obtains fast, miniband-like carrier extraction from the AR. Scattering due to IFR is taken into account to estimate an EL linewidth of 54.6 meV for this device. Utilizing both elastic and inelastic lifetimes, the $J_{\text{th}}$ value is projected to be as low as 1.4 kA/cm$^2$ for 3-mm-long, HR-coated devices. The thermal and optical characteristics of InAlAs-cladding and InGaP-cladding structures for the presented QCL design on MBLs are analyzed. InAlAs is computationally shown to be more effective than InGaP in confining the optical field as well as better for dissipating the generated heat. There is, however, a penalty in the heat dissipation of such a QCL owing to the requirement of a ternary cladding layer lattice matched to the MBL when compared to the InP-based QCLs employing InP claddings. Future work includes verification of the thermal conductivities of the specific compositions of InAlAs and InGaP grown on the MBL, and growth and characterization of QCLs with these cladding layers.
