Abstract. In agricultural remote sensing, unmanned aerial vehicle (UAV) platforms offer many advantages over conventional satellite and full-scale airborne platforms. One of the most important advantages is their ability to capture high spatial resolution images (1–10 cm) on-demand and at different viewing angles. However, UAV platforms typically rely on the use of multiple cameras, which can be costly and difficult to operate. We present the development of a simple low-cost imaging system for remote sensing of crop health and demonstrate it on lettuce (*Lactuca sativa*) grown in Hong Kong. To identify the optimal vegetation index, we recorded images of both healthy and unhealthy lettuce, and used them as input in an expectation maximization cluster analysis with a Gaussian mixture model. Results from unsupervised and supervised clustering show that, among four widely used vegetation indices, the blue wide-dynamic range vegetation index is the most accurate. This study shows that it is readily possible to design and build a remote sensing system capable of determining the health status of lettuce at a reasonably low cost (<US\$100). When combined with recent advances in UAV technology, this system could lead to yield increases for lettuce growers. © The Authors. Keywords: cluster analysis; crop health; lettuce; multispectral imaging; precision agriculture; vegetation index.

Paper 16637 received Sep. 8, 2016; accepted for publication Dec. 13, 2016; published online Jan. 11, 2017.

1 Introduction

To ensure that world food production can rise by 70% by 2050 to match our growing population, it is crucial that advances in crop-monitoring technology be made accessible and affordable to as many farmers as possible.¹ Satellite imaging methods have become increasingly sophisticated over the last few decades, but they still tend to suffer from inadequate image resolution, long satellite revisit intervals, and obstructions from the local weather.² Full-scale airborne imaging via airplanes and helicopters typically rely on multicamera/multispectral systems, which can be costly and difficult to operate, inhibiting their widespread adoption, particularly by farmers in developing countries.³ In this paper, a simple low-cost alternative is proposed in the form of a commercially available digital camera converted for use in remote sensing of crop health. This system works by detecting spectral reflectance changes in crops and using these as input in an expectation maximization (EM) cluster analysis (with a Gaussian mixture model) to generate early warning indicators of crop stress.⁴ The system is tested on lettuce grown in Hong Kong and is shown to be capable of discerning between healthy and unhealthy lettuce, thus providing lettuce growers with potential access to precision agriculture at a reasonably low cost (<US\$100).

Increased crop stress is known to decrease photosynthetic activity in the vegetative canopy.⁵ Chlorophyll pigments are the main determinants of vegetation reflectance.⁶ For many green vegetables, a deterioration of plant health leads to reflectance decreases in the near-infrared (NIR) range of the electromagnetic spectrum and to reflectance increases in the visible range.⁷ Vegetation indices that capture these contrasting NIR and visible wavelengths, such as the

*Address all correspondence to: Larry K. B. Li, E-mail: larryli@ust.hk

normalized difference vegetation index (NDVI), have been successfully used to discern between healthy and unhealthy crops.⁸ However, surprisingly little work has been done on lettuce (*Lactuca sativa*), with previous studies having relied on labor-intensive and costly spectroradiometers⁹ and artificial neural networks,¹⁰ or having focused on green coverage rather than health.¹¹

Recent advances in unmanned aerial vehicle (UAV) technology allow for remote sensing of vegetation at high spatial resolutions (1 to 10 cm) throughout much of the growing season.^{12,13} The high spatial resolution and weather insensitivity of these UAV platforms make them well suited for diagnosing the health of individual plants.¹⁴ When equipped with autonomous navigation systems, these UAV platforms can operate independently with minimal pilot or user input, transmitting data back to a central base station for real-time processing and analysis.^{15,16} This enables ameliorating measures to be customized on a plant-by-plant basis and then deployed at specific times, reducing in-field crop spoilage.¹⁷ Similarly, the knowledge that a particular plant is sufficiently healthy prevents over-irrigation and the overspray of fertilizers and pesticides. Thus, with UAV-based platforms, human interactions with the land (i.e., irrigation, fertilization, and pesticides application) would not only be better optimized in terms of volume, frequency, and costs, but it would also be possible to target individual plants rather than the field as a whole.¹⁸

In this study, a low-cost imaging system is developed and tested for low-altitude UAV-based remote sensing of lettuce health. The hardware is built around a commercially available digital camera that uses a charge-coupled device to capture crop-reflectance images via an optical filter. Once captured, the images are analyzed using an unsupervised EM clustering algorithm with a Gaussian mixture model. Section 2 describes the data collection process, camera conversion, selection of optical filters, and selection of vegetation indices for detection of lettuce health. Section 3 compares the performance of four vegetation indices at two camera angles (ground-level versus oblique views) and evaluates the accuracy of the clustering algorithm used to discern healthy from unhealthy lettuce. Section 4 summarizes the key findings of this study and provides an outlook for future improvements and potential applications.

2 Experimental Methodology

2.1 Field and Crop Selection

Experiments were conducted in *in-vitro* conditions at Eco-Park, Tseung Kwan O, Hong Kong from Jan to Jun 2016 (Fig. 1). Lettuce (*Lactuca sativa*) was selected as the test crop because of its prevalence throughout Asia, its relative ease of growth, and its potential role as a high-yield food source.¹⁹ Lettuce was also selected for its ability to showcase the high spatial resolution of the proposed imaging system. This plant has a broad leaf area when viewed from above, with growers tending to maintain a distinct separation between individual lettuce heads.²⁰

Lettuce seedlings were germinated for 4 weeks and then planted into a 1.5 m × 1 m sandy loam plot at Eco-Park, with a planting density of 9 plants per square meter. The lettuce grew under natural illumination, facing natural weather conditions in an outdoor environment, reproducing the conditions under which real crops grow. The lettuce was subjected to two conditions: optimal healthiness (8 plants) and suboptimal healthiness (11 plants). The former condition, which will be referred to as “healthy,” was achieved with an irrigation level of 100% (i.e., watering every 2 days), fertilized every 10 days with a peanut-based fertilizer containing nitrogen, protein, phosphorous, potassium, and calcium. The latter condition, which will be referred to as “unhealthy,” was achieved with an irrigation level of 50% (i.e., watering every 4 days) without any fertilizer. The first images were collected 120 days after initial planting.

2.2 Camera Conversion and Optical Filter Selection

Lettuce reflectance measurements were obtained by converting a commercially available point-and-shoot digital camera (Canon PowerShot A2200: 1/2.3-inch CCD sensor with 4320 × 3240 pixels) into a multispectral imager sensitive to both visible and NIR light. For agricultural

health monitoring, red wavelengths (640 nm) are generally preferred because of (i) their sensitivity to changes in plant health, (ii) the stronger absorption of blue light by chlorophyll and anthocyanin pigments, and (iii) the scattering of blue light by the atmosphere (i.e., Rayleigh scattering), which tends to reduce the signal-to-noise ratio.²¹

However, even when equipped with a red-pass filter, the red channel of most image sensors is usually contaminated with both red (640 nm) and NIR (700 to 1000 nm) light. This can be resolved with multicamera systems in which one camera is assigned to receive only red light and another is assigned to receive only NIR light. However, for low-cost single-camera setups, such as the one proposed here, a blue-pass filter can be used to separate red light from NIR light. Blue-pass filters are particularly suited for low-altitude imaging because the crop-to-camera distance can be made sufficiently short that signal contamination due to atmospheric Rayleigh scattering becomes negligible. For these reasons, the camera's built-in infrared-reflecting hot mirror was removed, and a Roscolux #2007 blue-pass filter was installed in its place to separate blue transmission (450 nm) from NIR transmission (700 to 1000 nm). As Fig. 2 shows, this optical filter has low transmittance in the red wavelengths (600 to 700 nm) but high transmittance in the NIR (700 to 1000 nm), and blue (450 to 500 nm) wavelengths. Equipped with these modifications, the red channel of the image sensor becomes an NIR channel, which will be used in Sec. 2.5 to compute various vegetation indices.

2.3 White Balance Calibration

Most digital cameras have white balance settings that are optimized for red, green, and blue (RGB) inputs.²² With the hot mirror removed and the Roscolux #2007 blue-pass filter installed, the blue channel now receives both blue and NIR light. To compensate for this, a blue calibration image was taken as the reference of the white balance, so that the camera digitally diminishes the blue channel intensities while increasing the red channel intensities. Calibration of the white balance of the camera was performed with *in-situ* lighting conditions.

2.4 Image Sampling

Spectral images of lettuce were taken under natural illumination, with the camera 0.5 m away from the plant leaf surface. The white balance was recalibrated with each measurement using a blue reference image, as per Sec. 2.3. The compact nature of this imaging system makes it ideal

Fig. 2 Transmittance of the Roscolux #2007 blue-pass filter, as measured *in situ* using a USB-650 VIS-NIR Red Tide spectrometer connected to SpectraSuite, both produced by Ocean Optics. A tungsten-filament lamp was used as the white-light source for reference illumination.

for top-down sweeps with low-altitude UAVs or side-on panoramas conducted on foot or on autonomous vehicles. To assess the sensitivity of this system, both top-down and side-on views were captured of each plant, as shown in Fig. 3. The side-on images were taken with the camera horizontal to the lettuce. The top-down images, representing typical UAV-based measurements, were taken with the camera tilted at 30 deg from the vertical.

2.5 Selection of Vegetation Indices

As explained in Sec. 2.2, the proposed imaging system cannot distinguish between red and NIR light. This restricted our choice of possible candidates for the optimal vegetation index to those that use either blue or green light, as well as NIR light. Four candidate indices were selected from

Table 1 Vegetation indices selected for evaluation on lettuce.

Vegetation index	Equation
Blue-normalized difference vegetation index ²⁴	$\frac{\text{NIR}-\text{BLUE}}{\text{NIR}+\text{BLUE}}$
Blue wide-dynamic range vegetation index ²⁵	$\frac{\alpha \text{NIR}-\text{BLUE}}{\alpha \text{NIR}+\text{BLUE}}$
	$\alpha \in [0.1, 0.2]$
Green chlorophyll index ²⁶	$\frac{\text{NIR}}{\text{GREEN}} - 1$
Green-normalized difference vegetation index ²⁴	$\frac{\text{NIR}-\text{GREEN}}{\text{NIR}+\text{GREEN}}$

Fig. 4 Typical reflectance spectra for healthy and unhealthy lettuce (*Lactuca sativa*).¹⁰

the literature, as shown in Table 1. Typical reflectance spectra for healthy and unhealthy lettuce are shown in Fig. 4. It can be seen that the blue reflectance changes little between health statuses, but that the NIR reflectance changes markedly. One of the most widely used vegetation indices, the NDVI, has in its numerator the intensity difference (NIR – RED). Therefore, the NDVI would be large for healthy lettuce but small for unhealthy lettuce, making it a particularly sensitive indicator of plant health.²³ By contrast, the blue-normalized difference vegetation index (BNDVI) uses blue light and the green-normalized difference vegetation index (GNDVI) uses green light, which means that neither would be as sensitive as the NDVI. Nevertheless, the NDVI cannot be used here because it requires a pure red channel, which is unavailable from the proposed blue-green imaging system. Consequently, only vegetation indices that use blue or green light were tested (see Table 1).

2.6 Image Processing

Figure 5 shows the steps in the image processing procedure. The first step was to automatically crop the lettuce from its background so that the calculated vegetation index pertained only to the lettuce itself [Figs. 5(i) → 5(ii)]. Next, the images were processed through a MATLAB script that calculated the vegetation index of each pixel and produced a spatially averaged index for the whole image [Figs. 5(ii) → 5(iii)]. These steps were then repeated for each of the four vegetation indices listed in Table 1.

Fig. 5 Steps in the image processing procedure: (i) → (ii) cropping of the lettuce plant and (ii) → (iii) computation of the vegetation index. In this example, BWDRVI values are shown on the colorbar to the right.

2.7 Data Analysis: Supervised and Unsupervised Clustering

The vegetation indices computed in Sec. 2.6 were analyzed for plant health using an unsupervised EM clustering algorithm and a Gaussian mixture model.²⁷ This iteratively analyses the input data to find two distinct clusters blindly from a pooled set of healthy and unhealthy plant data.²⁸ With the assumption that the data obeys a normal distribution, Gaussian fits were assigned to the two clusters. The data were used as a training set for the EM Gaussian mixture model. This method is a generalizable procedure that accepts processed images of any given plant and returns a probability of it being healthy, provided that a training set for this particular species exists.²⁸ This is a process that eliminates bias and offers quantitative measures of plant health.⁹

The vegetation indices were passed into `fitgmdist` (a built-in function in MATLAB) to produce two Gaussian curves without any knowledge of the health status of each index value. The two curves enable probabilistic assignment of any index value to a cluster, as well as providing a measure of the contrast between healthy and unhealthy lettuce. For evaluation of the clustering quality, the healthy and unhealthy data for each vegetation index were also used in a supervised cluster analysis to manually create two Gaussian curves, providing a known baseline reference against which the unsupervised clustering results could be compared.

In summary, our objective is to determine the most accurate vegetation index for discerning optimally healthy lettuce from suboptimally healthy lettuce using the multispectral images captured with our low-cost camera system (Sec. 2.2). As will be discussed in Sec. 3, by selecting the index that provides the sharpest contrast between healthy and unhealthy lettuce, we were able to create an unsupervised EM Gaussian model for objective diagnosis of lettuce health.

3 Results and Discussion

3.1 Comparison of Vegetation Indices

Comparing the unsupervised and supervised clusters (specifically, their means and variances) and the errors between them provides an objective indicator of the most accurate vegetation index to be paired with the proposed imaging system. This comparison is shown in Figs. 6–9. Of the four indices tested, the blue wide-dynamic range vegetation index (BWDRVI) is the most capable of discerning healthy from unhealthy lettuce, as indicated by (i) the close match between the unsupervised and supervised clustering curves, at both camera angles [Figs. 7(a) and 7(b)

Fig. 6 Supervised and unsupervised clustering of BNDVI values. (a and b) The supervised clustering, (c and d) the unsupervised clustering, and (e and f) a histogram of bootstrapped means. The left column is for the side-on view, and the right column is for the top-down view.

Fig. 7 Supervised and unsupervised clustering of BWDRVI values. (a and b) The supervised clustering, (c and d) the unsupervised clustering, and (e and f) a histogram of bootstrapped means. The left column is for the side-on view, and the right column is for the top-down view.

versus Figs. 7(c) and 7(d)]; and (ii) the distinct separation between the Gaussian peaks of the healthy and unhealthy lettuce [Figs. 7(a) and 7(c) versus Figs. 7(b) and 7(d)].

To further demonstrate the superiority of BWDRVI, we define an accuracy index (AI) that quantifies the ability of a vegetation index to correctly identify any lettuce data point as belonging to either a healthy or an unhealthy cluster:

Fig. 8 Supervised and unsupervised clustering of green chlorophyll index values. (a and b) The supervised clustering, (c and d) the unsupervised clustering, and (e and f) a histogram of bootstrapped means. The left column is for the side-on view, and the right column is for the top-down view.

$$AI \equiv \frac{\text{Number of correctly assigned data points}}{\text{Total number of data points}}. \quad (1)$$

For each of the four vegetation indices (Table 1), AI values were calculated by classifying the data as belonging to either healthy or unhealthy clusters on the basis of the maximum posterior

Fig. 9 Supervised and unsupervised clustering of GNDVI values. (a and b) The supervised clustering, (c and d) the unsupervised clustering, and (e and f) a histogram of bootstrapped means. The left column is for the side-on view, and the right column is for the top-down view.

probability.²⁹ In this way, an AI value was generated for each vegetation index, as shown in Fig. 10. It can be seen that images taken from the top-down perspective and processed through BWDRVI produce the most distinct clusters and can therefore be used to determine, with the highest accuracy, the health status of lettuce. Furthermore, when mixing top-down and side-on

Fig. 10 Accuracy index [Eq. (1)] for the four vegetation indices listed in Table 1, at two different camera angles (side-on and top-down views).

camera angles, BWDRVI still emerges as the most accurate vegetation index, which is consistent with the observations seen in Fig. 7.

3.2 Bootstrap Resampling

A bootstrap resampling analysis was performed with 20,000 resamples in order to gain further statistical confidence on the results. Subfigures (e) and (f) of Figs. 6–9 show the histograms of the means of the bootstrapped resamples. The close correspondence of the histograms in Figs. 7(e) and 7(f) to their respective Gaussian curves in Figs. 7(c) and 7(d) confirms that BWDRVI is indeed well suited for unsupervised cluster analysis of lettuce health.

4 Conclusions

A simple low-cost imaging system was developed and tested for low-altitude remote sensing of lettuce health. Built with off-the-shelf components, the system was designed with the strategic aim of increasing the adoption rate of precision agriculture, by making crop-monitoring technology more affordable and accessible, particularly to farmers in developing countries.

Despite its simplicity and low cost, the proposed imaging system was shown to be capable of discerning between healthy and unhealthy lettuce grown in a field plot in Hong Kong. Unsupervised cluster analysis of the BWDRVI produced the most accurate Gaussian curves, as indicated by a high accuracy index of 88.89%. The method outlined here is effective at low altitudes and with different camera viewing angles, making it particularly well suited for deployment on UAV platforms. This study shows that accurate remote sensing of lettuce health can be achieved through relatively simple and affordable means (<US\$100). When combined with recent advances in UAV technology, the proposed system could lead to yield increases for lettuce growers.
