Abstract. The Extreme-ultraviolet Stellar Characterization for Atmospheric Physics and Evolution (ESCAPE) mission is an astrophysics Small Explorer employing ultraviolet spectroscopy (EUV: 80 to 825 Å and FUV: 1280 to 1650 Å) to explore the high-energy radiation environment in the habitable zones around nearby stars. ESCAPE provides the first comprehensive study of the stellar EUV and coronal mass ejection environments that directly impact the habitability of rocky exoplanets. In a 20-month science mission, ESCAPE will provide the essential stellar characterization to identify exoplanetary systems most conducive to habitability and provide a roadmap for NASA's future life-finder missions. ESCAPE accomplishes this

*Address all correspondence to Kevin France, kevin.france@colorado.edu

goal with roughly two-order-of-magnitude gains in EUV efficiency over previous missions. ESCAPE employs a grazing incidence telescope that feeds an EUV and FUV spectrograph. The ESCAPE science instrument builds on previous ultraviolet and x-ray instrumentation, grazing incidence optical systems, and photon-counting ultraviolet detectors used on NASA astrophysics, heliophysics, and planetary science missions. The ESCAPE spacecraft bus is the versatile and high-heritage Ball Aerospace BCP-Small spacecraft. Data archives will be housed at the Mikulski Archive for Space Telescopes. © The Authors. 1 Introduction

Owing to their large number and strong atmospheric impacts, extreme ultraviolet (EUV) photons are the primary agent driving atmospheric escape on planets orbiting cool stars (F, G, K, and M stars; ~ 2 to 0.1 solar masses). The stability of Earth-like atmospheres critically depends on the EUV irradiance.^{1,2} Higher EUV flux from the young Sun³ could have led to 10 $\times$ greater oxygen loss rates and 90 $\times$ greater carbon loss rates on the early Martian atmosphere, compared to present day levels, by increasing the suprathermal or “hot” population of these atoms.⁴ On highly irradiated planets, the outflow is sufficiently rapid that heavier atmospheric species (e.g., N, C, O, Mg, and Fe) can be dragged along through collisions with the lighter hydrogen, as observed even on hot Jupiters.^{5–11} Free electrons produced by stellar EUV photons can also attain altitudes much greater than ions, producing an ambipolar electric field that leads to a non-thermal ionospheric outflow in O⁺ and N⁺ winds.^{12–15} Consequently, a major open question as astronomers embark on the spectral characterization of rocky exoplanets in the coming decade with James Webb Space Telescope (JWST) is whether terrestrial atmospheres can survive the radiation environments around other stars.¹⁶

Previous EUV observatories have lacked the sensitivity to survey exoplanet host stars in this spectral band, and as a result, widely discrepant techniques have been employed to approximate the critical stellar inputs into exoplanet atmosphere models. In this paper, we present the motivation for and the mission overview of the extreme-ultraviolet Stellar characterization for atmospheric physics and evolution (ESCAPE) mission. ESCAPE explores the habitable zone (HZ) radiation environment around more than 200 nearby stars, filling the observational gap in planetary atmosphere evolution models, models that enable us to predict which star-planet systems are most promising for developing and maintaining habitable conditions. These nearby stellar systems make up the target list for future NASA missions focused on spectroscopic characterization of rocky planets.

ESCAPE investigates stars of spectral types F, G, K, and M to be responsive to all terrestrial exoplanet characterization missions currently in implementation or formulation. Terrestrial exoplanet research with JWST in the 2020s and the Origins Space Telescope (OST) or an infrared (IR) probe in the 2030 s are best suited to study transiting exoplanets around M dwarfs. Direct detection missions of the 2030 and 2040s, such as Habex, LUVOIR, and the 6-m UVOIR mission recently recommended by the Astro2020 Decadal Survey will be optimized for exo-Earths orbiting more massive F, G, and K stars. ESCAPE’s observing program provides the stellar EUV context for whatever technical and programmatic approach the community adopts to identify and characterize habitable worlds. The ESCAPE data set will allow the astronomical community to predict the most promising star-planet systems for life detection missions in the coming decades, establishing a roadmap for future observing resources to explore habitable worlds.

2 Science Objectives and Implementation

ESCAPE's primary science goal is to identify and understand those star-planet systems that are conducive to the formation of habitable environments. The ESCAPE mission addresses this goal by answering three key science questions:

1. What is the EUV irradiance in the HZ?
2. How does stellar EUV irradiance evolve in time?
3. What are the properties of stellar coronal mass ejections (CMEs)?

ESCAPE addresses these science questions through a comprehensive observing program supported by state-of-the-art planetary atmosphere models that take ESCAPE's observables as inputs and are used to estimate atmospheric mass loss rates from representative terrestrial planets. The ESCAPE instrument: (1) achieves $\approx 25\times$ to $100\times$ the EUV efficiency of previous missions, resolving order-of-magnitude uncertainties on exoplanet radiation environments; (2) explores EUV variability from flares, stellar rotation, and stellar evolution with its photon-counting detector, monitoring survey, and sample of F, G, K, and M stars with a range of ages; and (3) executes the first survey of stellar CMEs using techniques validated in "Sun-as-a-star" measurements by NASA's Solar Dynamics Observatory-EUV Variability Experiment EVE (SDO-EVE) instrument, providing direct constraints on exoplanet particle environments.

3 High-Energy Radiation Environments: EUV Photons, Variability, and CMEs

3.1 Stellar EUV Irradiance

Optical and near-infrared photons heat the surface and troposphere. NUV (1800 to 3200 Å), FUV (912 to 1800 Å), and x-ray (5 to 100 Å) photons are absorbed in the middle and upper atmosphere where they photo-dissociate molecules and ionize heavy elements. EUV photons (100 to 911 Å) are absorbed high in the atmosphere (i.e., in the thermosphere) where they ionize atoms and molecules. Liberated electrons collisionally heat the surrounding gas, increasing the scale height of the atmosphere, driving ambipolar ion mass loss, and potentially leading to the formation of a hydrodynamic outflow. Rapid atmospheric loss can lead to both desiccation and the build-up of abiotic O₂ atmospheres that complicate biosignature searches.^{17–19}

EUV photons are the key drivers for atmospheric mass-loss for three primary reasons: (1) EUV photons are absorbed in the highest (lowest density) layers of the atmosphere, where radiative losses (proportional to density squared) are minor and the heating efficiency is highest, (2) the ionization cross-sections for dominant upper atmospheric atomic species (e.g., H, N, and O) peak at EUV wavelengths, and (3) there are many more EUV photons than x-rays available on all types of stars to drive this heating. In the quiet Sun, the EUV/x-ray photon production ratio is ~ 90 .²⁰ For optically inactive early M dwarfs, the EUV/X-ray photon ratio is ~ 40 ,²¹ and even for an active late M dwarf like Proxima Cen, the EUV/x-ray photon ratio is ~ 16 (Fig. 1).

The discovery of rocky planets in the HZs of nearby stars, e.g., Proxima Cen b and the TRAPPIST-1 planets, has motivated new atmospheric mass loss calculations that highlight the need for improved EUV irradiance data to estimate their long-term habitability. Garcia-Sage et al.²⁸ and Airapetian et al.²⁹ presented studies of EUV-driven ion loss from Earth-like planets orbiting M dwarfs. They found mass loss rates several orders of magnitude higher than that of present-day Earth for EUV fluxes 10 to 20 times the current day EUV solar irradiance. Their models indicate that elevated EUV fluxes, augmented by persistent flares or the long pre-main-sequence phase of M dwarfs, could effectively render some Earth-like planets around M dwarfs devoid of an atmosphere, in the absence of internal or external resupply of volatiles. A factor of ten in the uncertainty of incident EUV flux can lead to three orders of magnitude in the uncertainties of ion escape rates,²⁸ fundamentally shifting our predictions for which exoplanets are the best candidates for long-lived habitable atmospheres.

Fig. 1 (a) Composite spectrum of the nearby planet-hosting M dwarf Proxima Cen, adapted from France et al. (2016)²² and Loyd et al. (2016)²³. The width of the shaded region indicates the approximate uncertainty on the intrinsic flux level. (b) Different reconstructions of the EUV spectrum of Proxima Cen show factors of 3 to 100 flux discrepancies: differential emission measure models in red, blue, and gray (Drake et al. 2020);²⁴ scaling relations based on only FUV data in black (Linsky et al. 2014)²⁵ and only x-ray data in orange (Sanz-Forcada et al. 2011).²⁶ (c) The corresponding atmospheric hydrogen mass lost from an Earth-like planet (in units of Earth oceans; 1 Earth ocean = 1.4×10^{24} g) from 10 Myr to 4.8 Gyr for high (shaded gray) and low (hatched) EUV histories of typical M dwarfs (Ribas et al. 2017).²⁷

Figure 1 shows the results of analogous thermal atmospheric escape calculations for Proxima Cen b under different plausible EUV radiation strengths and histories. Model calculations yield a factor of ~ 30 spread in the total atmospheric mass loss from the planet over time, driven almost entirely by what assumptions are used to estimate the current EUV flux and its evolution earlier in the star's history.

Despite their importance, the EUV luminosity, flare rate, and evolution of other stars are almost completely unconstrained and can only be empirically determined with direct measurements of the EUV flux and temporal variability of a sample of stars with a range of ages and activity levels. Existing EUV spectra of exoplanet host stars are scarce. The only previous EUV astronomy mission, the extreme ultraviolet explorer (EUVE; Bowyer³⁰ and Malina 1991), obtained spectra of ~ 15 cool main sequence stars, including 5 M dwarfs. EUVE's observations were heavily biased toward the most active stars. The very modest ≤ 2 cm² peak effective area of the EUVE spectrometers precluded useful spectroscopic observations of stars with more solar-like activity, except for the nearby α Cen system and the F4 subgiant Procyon.^{31,32} No observed EUV spectra exist of the optically inactive M dwarfs (defined here as Ca II H and K equivalent widths < 1 Å),^{22,33} which will be optimal for atmospheric studies with JWST, 30-m telescopes, and the Origins Space Telescope. The lack of direct EUV data hampers our ability to understand how habitable atmospheres evolve with time and to design truly definitive biosignature searches.

3.2 EUV Evolution and Flares

Solar EUV emission varies by factors of up to ~ 100 on minute timescales due to flares and by factors of ~ 6 on year timescales due to the solar cycle.³⁴ Different emission lines and continua vary by different factors on all timescales, whereas connections between the flare energy and

frequency distribution of white light flares [such as those observed with Kepler/*K2* and Transiting Exoplanet Survey Satellite (TESS)] and UV flares remain poorly constrained by observation and theory.^{35–38} Estimates of the EUV response of the Great AD Leo Flare of 1985³⁹ observed with the International Ultraviolet Explorer indicate that the atmospheres of planets orbiting very active stars with frequent flares never achieve a steady state because the timescales for atmospheric recovery are much longer than the time between successive flares.⁴⁰ EUVE provided constraints on flare frequencies for a small sample of young, active stars,⁴¹ however, the lack of direct constraints on EUV flare activity on older stars (e.g., France et al. 2020)⁴² hinders our ability to model the stability of potentially habitable atmospheres over timescales required for the initial development of surface life (~ 1.7 Gyr; Jones and Sleep).⁴³ ESCAPE employs a photon-counting detector to record all observations in a “time-tagging” mode that provides temporal resolution (<20 s, limited by photon statistics, the instrumental timing resolution is <0.1 s) higher than the characteristic UV flare duration on low-mass stars (~ 300 s; Hawley et al. 2003; Loyd and France 2014; Loyd et al. 2018a).^{44–46}

Characterization of the EUV flare frequency and spectral variability on stellar evolutionary timescales requires (1) directly collecting EUV spectra over long enough temporal baselines to monitor variability and (2) a broad sample of stars with a range of masses and ages (activity levels, e.g., West et al.).⁴⁷ The required monitoring observations cannot be collected from the ground because of the lack of optical features whose behavior is closely linked to the EUV emission. For example, inactive M dwarfs that show little optical lightcurve variation at the $<1\%$ level can display factors of ~ 50 increases in the FUV and x-ray,^{22,46} and we expect the behavior to be similar at EUV wavelengths. ESCAPE employs a dedicated monitoring program to sample the flare frequency and energy distribution for individual systems across spectral classes and ages (Sec. 5).

3.3 Detecting Stellar CMEs

High-energy particles have a major influence on the evolution of exoplanetary atmospheres, both through the actions of stellar winds and impulsive events (e.g., CMEs). While stellar winds play a part in atmospheric escape, CMEs are thought to be the dominant source of long-term instability in planetary atmospheres.^{48–50} The influence of CMEs depends strongly on their frequency and ability to break out of coronal magnetic confinement; ESCAPE will measure the frequencies of CMEs on solar-type stars and search for CME breakout from M dwarfs.

While the main source of heat in the upper atmosphere of planets is the EUV flux, Joule heating and particle precipitation heating could dominate the chemical impact of impulsive events (e.g., Segura et al. 2010³⁵ and Tilley et al. 2019).⁵¹ CMEs deliver heat to the upper atmospheres of orbiting planets through charge exchange reactions.⁵² Pickup and sputtering processes can also be major sources of atmospheric loss from direct particle precipitation and stellar wind enhancements due to CMEs. CMEs contribute to atmospheric mass loss on solar system planets^{53,54} and to space weather, leading several authors to propose an expanded definition of the HZ that takes into account space weather impacts (e.g., Airapetian et al. 2017 and 2020)^{15,29} as more meaningful than the traditional liquid water HZ.

About $\sim 90\%$ of large (X-class) solar flares are associated with CME-like particle eruptions,⁵⁵ however, this connection has not been borne out with recent observations of stellar flares.^{56–58} While the EUV irradiance is increased by a large flare rate, CMEs and accelerated particles may have much greater impacts on atmospheric photochemistry and stripping than the flare radiation itself.^{35,49}

For the Sun, we are able to observe CMEs directly with coronagraphs and *in situ* measurements. These traditional methods are not feasible for stellar CMEs in the near-term (although see Haisch et al. and Moschou et al.).^{59,60} However, other techniques for detecting solar CMEs have been developed. Harra et al.⁶¹ reviewed these techniques and determined that coronal dimming, described below, is the only feature consistently associated with CMEs that can be employed to detect and quantify these events on other stars.

Solar coronal dimming studies have primarily relied upon spatially resolved EUV images to characterize the transient voids left behind in the corona as a CME departs, giving rise to the observed flux dimming (e.g., Sterling and Hudson, Aschwanden et al., Reinard and Biesecker;

Fig. 2 (a) Observation of coronal dimming in full-disk solar spectra and (b) angularly resolved filter imaging. The spectrally resolved lightcurves from SDO-EVE show flaring lines (Fe XV 284 Å, green) and the corrected Fe IX 171 Å dimming profile in black (Mason et al. 2016).⁶⁸ ESCAPE is sensitive to similar events on F, G, and K dwarfs to a distance of 6 pc. More than 90 candidate events are expected in the DEEP survey (Sec. 5.2).

Dissauer et al. 2018a,b).^{62–66} The SDO-EVE, Woods et al. 2012,³⁴ demonstrated that dimming can also be characterized in disk-integrated EUV spectra.^{67–70} Similar dimming events have recently been reported in x-ray lightcurves of active stars and an archival EUVE spectrum of the young K star AB Dor.⁷¹ ESCAPE employs the same Sun-as-a-star stellar CME characterization techniques validated on SDO-EVE (Fig. 2) to measure the frequency of CMEs on nearby stars for the first time.

The dimming light curve also contains information about the kinematics of the CME that produced it. Solar dimming lightcurves have been calibrated by in-situ proton measurements and coronagraphic imaging of CMEs. The depth of the dimming event is directly related to the mass of the ejected CME (the dispersal of the quiescent corona greatly reduces the emission measure, which scales as density squared), whereas the slope of the dimming lightcurve indicates the CME propagation velocity.^{68,69} Therefore, observations of coronal dimming events on solar-type stars can provide direct constraints on the physical properties of the CME.

4 Interstellar Attenuation and Flux Reconstruction

Dust and molecular hydrogen extinction is negligible within the local cavity (Lehner et al.,⁷² also historically referred to as the local bubble), meaning that the only significant sources of line-of-sight opacity (or, reddening) are neutral and low-ionization atomic gases.⁷³ The ESCAPE FUV bandpass covers 1280 to 1650 Å (excluding the strong Ly α line); the only significant sources of interstellar opacity in the FUV band are neutral oxygen and singly ionized carbon and silicon, which impact measurements of low-ionization lines in ESCAPE FUV range (e.g., C II). In ESCAPE EUV range, neutral hydrogen (H I), neutral helium (He I), and ionized helium (He II) contribute, with the H I column density being the controlling parameter for the total line-of-sight EUV extinction (Fig. 3). Despite the physical complexity of the local ISM, integrated H I column density rarely exceeds $10^{18.4}$ cm⁻² within 30 pc of the Sun⁷⁴ and do not reach 10^{19} cm⁻² routinely until $d > 80$ pc, beyond ESCAPE's baseline mission target distance.

ESCAPE employs three techniques to measure or estimate the interstellar hydrogen column density [N(HI)] toward its targets and therefore to correct for the ISM attenuation in its spectra. First, high-fidelity direct measurements of N(HI) are routinely acquired with the HST-STIS instrument (or archival data from *HST*-GHRS). Direct Lyman- α measurements of N(HI) yield uncertainties of <0.1 dex (see, e.g., Table 2 of Wood et al. 2005,⁷⁴ Tables 2 and 3 of Youngblood et al. 2016).⁷⁵ Second, an all-sky n(HI) map created from ensemble archival N(HI) measurements has been created and subsequently validated by comparing new observations from Hubble Space Telescope (HST)⁷⁶ against the predicted N(HI) from the all-sky map, finding agreement between

Fig. 3 Transmission of the local interstellar medium for H I column densities typical of stars inside 30 pc ($10^{17.6-18.4} \text{ cm}^{-2}$; Wood et al. 2005).⁷⁴ These curves demonstrate that the ISM is more than 20% transparent to EUV photons over most of the ESCAPE G20 and G40 bandpasses for most stars inside 30 pc.

direct observation and all-sky model prediction of ≤ 0.25 dex. This level of interstellar column uncertainty yields absolute flux uncertainties $\leq 35\%$ for wavelengths shorter than 300 Å and column densities typical of the local ISM within 30 pc ($\leq 10^{18.4} \text{ cm}^{-2}$). Finally, these empirical techniques are augmented by three-dimensional ISM models based on empirical studies of the local ISM and publicly available to the community (Ref. ⁷³). The ISM models of Redfield and Linsky (Ref. ⁷³) predict the line-of-sight column density through the local ISM for an arbitrary look direction.

Stars within 30 pc encompass almost all HZ planets that are candidates for spectroscopic characterization and biomarker detection (LUVOIR Team Final Report⁷⁷). ESCAPE has the sensitivity to meet the required signal-to-noise and temporal resolution to address the key science questions (Sec. 2) for F, G, K, and active M stars out to 30 pc and inactive stars earlier than M5 out to 8 pc. Thus, the interstellar medium is not the limiting factor in our ability to study EUV emission from the most important exoplanet hosts.

ESCAPE obtains accurate measurements of the 80 to 560 Å spectrum of nearby cool stars in the primary EUV channels. The 570 to 911 Å flux is also important for exoplanet heating calculations as this band overlaps with the peak of the ionization cross-sections of atomic and molecular hydrogen. However, attenuation by the local ISM in the 570 to 911 Å region prevents observations from all but the very nearest stars with the lowest ISM column density sightlines.

ESCAPE takes a two-tiered approach to measuring these important intermediate EUV wavelengths. (1) ESCAPE's simultaneous coverage of coronal and transition region lines from 80 to 560 Å and transition region and chromospheric lines in the FUV channel from 1300 to 1650 Å (e.g., C II, Si IV, and C IV) provide robust constraints on differential emission measure calculations (DEM; see, e.g., Drake et al. 2020;²⁴ Duvvuri et al.⁷⁸ and references therein), allowing us to calculate accurate stellar fluxes in the 570 to 911 Å region. (2) ESCAPE includes a low-resolution mode covering 600 to 825 Å with sufficient sensitivity to directly measure stellar emission in this bandpass, including the important H I Lyman continuum, for ~ 10 stars in the DEEP survey (The 565 to 600 Å and 825 to 911 Å regions are avoided due to bright He I 584 Å and O II 834 Å geocoronal airglow emission, respectively.).

5 ESCAPE Science Surveys: SEEN and DEEP

5.1 Stellar EUV ENVironments Survey

The Stellar EUV ENVironments (SEEN) survey measures the 80 to 1650 Å irradiance and time variability for 200 stars with absolute photometric uncertainty $< 40\%$ in the 20 month baseline mission. The photometric accuracy requirement is selected to remove the stellar flux as a dominant source of uncertainty in atmospheric escape calculations.¹⁶ We require the sensitivity and spectral resolution to separate stellar emission lines and measure variability in individual spectral

Fig. 4 A simulated *ESCAPE* SEEN spectrum of Proxima Cen is shown (black). The 77ks EUVE exposure of Proxima Cen (green, offset by 500 counts) resulted in tentative detections of ~ 5 stellar emission lines. *ESCAPE* achieves a line-integrated S/N of ~ 41 at Fe IX 171 Å in 35 ksec. Prominent iron ionization states are labeled in red and other species in blue.

features. These requirements drive the telescope size and grazing incidence design to maintain high throughput at EUV wavelengths (Sec. 6). To illustrate the comparison of a SEEN survey observation with archival data available from EUVE, we show a simulated raw spectrum of Proxima Cen in Fig. 4.

About ~ 20 flares are required to develop a flare-frequency distribution with $\sim 50\%$ logarithmic rate accuracy (e.g., the rate constant of the flare-frequency power-law distribution). To determine the required SEEN survey duration that effectively constrains the flare rates of F, G, K, and M dwarfs, we estimate the EUV flare rate based on the FUV flare-frequency distribution of Loyd et al. (2018a)⁷⁹ and the FUV-to-EUV scaling relations from France et al. (2018).⁸⁰

The flare frequency distribution is a power law, so more low energy flares are expected than high energy flares. Taking an intermediate activity M dwarf at 10 pc as our fiducial system, we find flares with total Fe IX 171 Å energy $E(\text{Fe IX}) \geq 5 \times 10^{29}$ erg produce a 5- σ flare detection with *ESCAPE* (assuming a typical 5-min M dwarf UV flare duration). This fiducial flare corresponds to a factor of ~ 15 brightening, typical for transition region flares observed on low-mass stars.^{44,46,79}

From the estimated EUV flare rate, we find that in a 35 ksec SEEN observation, we expect to detect 9 flares with 15 $\times$ brightening $E(\text{Fe IX}) = 10^{29.75}$ ergs; 3 flares with 50 $\times$ brightening $E(\text{Fe IX}) = 10^{30.25}$; and 1 flare with 100 $\times$ brightening $E(\text{Fe IX}) = 10^{30.55}$. To assemble statistically significant EUV flare-frequency distributions (≥ 20 flares), we will group 3 to 5 stars with similar mass and age properties. Flaring rates and fluxes of young G and K stars are comparable to intermediate activity M stars,^{15,81} therefore, we expect young G and K stars to be well represented by the inactive M dwarf calculations presented above.

ESCAPE measures the critical pre-main sequence history of M dwarf EUV luminosities,^{82,83} as well as the evolution of the EUV luminosity of F, G, and K stars (e.g., Johnstone et al. 2021; Fig. 5). The SEEN Survey covers a range of ages of each spectral type, spanning pre-main-sequence stars in the TW Hya and β Pic moving groups (ages < 30 Myr), intermediate age clusters such as the AB Dor and the Hyades (hundreds of Myr; Schneider et al.),⁸⁴ and “field” age stars comparable to the Sun (Gyr, based on gyrochronology and UV/optical activity indicators). Each spectral type is broken down into approximate “early” (subclass 0 to 4) and “late” (subclass 5 to 9) subgroups, e.g., [early F type stars (F0V to F4V), late-F type stars (F5V to F9V), early G type stars (G0V to G4V), etc.]. The SEEN survey data allow us to assess how similar the EUV outputs of two stars of comparable mass and age are, and importantly, allows us to develop a range of EUV flux estimates for a given set of basic stellar parameters that provides empirical bounds for studies of exoplanets beyond the lifetime of the *ESCAPE* mission.

A full 200-star target list that meets these requirements at sufficient S/N is shown in Figs. 5 and 6. About 41 of the baseline stars host known planets (with 85 total planets, 15 of which are in the 200 K to 330 K temperate zone). While this target list satisfies *ESCAPE*’s science objectives, ongoing results from TESS and Characterising Exoplanets Satellite (CHEOPS) will inform the final target list that will be finalized prior to launch. Finally, it should be noted that exoplanet populations statistics tell us that many of *ESCAPE*’s “planetless” target stars likely host planets

Fig. 5 Estimated range of the EUV radiation field on stellar evolutionary timescales, characterized in ESCAPE's SEEN survey. The EUV luminosity is the estimated 90 to 360 Å intrinsic luminosity and the symbol sizes represent the integrated S/N of Fe IX in a 35 ksec SEEN observation. Stars with confirmed exoplanets are shown as triangles. This plot shows our current 200 star target list, with resolution in both age and mass (color-coded).

Fig. 6 The ESCAPE target list consists of 41 known exoplanet host stars, and is representative of the underlying known exoplanet population. (a) The known exoplanet population is shown as bolometric flux received against the host star's effective temperature. (b) The known exoplanet population is shown as distance against stellar effective temperature. Solar system planets are shown as large gray/white circles, exoplanets are shown as small grey circles, and ESCAPE planned targets are blue squares (filled = known exoplanets, empty = no exoplanets yet known). An approximate estimate for the temperate zone (recent-Venus to early Mars; Kopparapu et al. 2013)⁸⁷ is shown as the gray shaded region.

that are yet to be detected (Dressing and Charbonneau; Stark et al. and references therein).^{85,86} Future direct-detection missions (e.g., LUVOIR and Habex) will both find and characterize these Earth-like planets around nearby solar-type (F, G, and K) stars. ESCAPE's SEEN survey ensures that when planets are directly imaged around these stars and spectroscopic characterization begins, the fundamental stellar constraints on the long-term stability of their atmospheres will be in place.

5.2 Dedicated EUV Eruption Program

The Dedicated EUV Eruption Program (DEEP) survey executes monitoring campaigns of 24 select stars to measure EUV flare frequency distributions and CME rates on individual, high-priority targets in the solar neighborhood.

ESCAPE measures the EUV flare frequency distribution of carefully selected F, G, K, and M dwarf systems on temporal baselines of ~ 20 to 40 times longer than the best available datasets from HST. Similarly, there has only been one comparable M dwarf campaign at x-ray wavelengths (0.15 to 15 keV; Kowalski et al. – in prep), and these data do not sample the 10^{5-6} K emission that contributes the majority of the stellar EUV flux.⁸⁸ Archival Kepler and TESS observations of white-light flares may also provide connections between the optical and EUV frequencies of superflares (e.g., Loyd et al. 2018b;⁴⁶ Howard et al. 2020).³⁸

The average CME rate of the Sun is ~ 3.5 CME day⁻¹ and is ~ 10 CME day⁻¹ at solar maximum.⁸⁹ The Sun is less active than other stars of its type (e.g., Reinhold et al. 2020),⁹⁰ so we conservatively estimate a CME rate of 5 CME day⁻¹ for Sun-like stars. Stellar CME rates are likely well-approximated by a Poisson distribution like the Sun, so the uncertainty on the CME frequency per day is the square root of the number of CMEs observed in a monitoring campaign divided by the monitoring duration. Therefore, observing nine CMEs results in a $3\text{-}\sigma$ constraint on the CME rate. While not every CME is preceded by a dimming event, most are. Veronig et al. find that 97% of CMEs have a corresponding irradiance dimming. However, only $\sim 50\%$ of those will occur on the observable side of the star. Finally, approximately one-third of all solar dimming events meet *ESCAPE*'s $3\text{-}\sigma$ spectrophotometric detection threshold (dimming depths $\geq 6\%$ in Fe IX 171 Å and Fe X 174 Å). Combining the above numbers with *ESCAPE*'s DEEP survey observing efficiency (78%), the expected detection rate for solar-like CMEs with *ESCAPE* is approximately 0.63 CMEs/day. *ESCAPE* will monitor each star in the DEEP survey for ≈ 14 days to provide sufficient temporal baselines to observe nine CMEs/target, resulting in a $3\text{-}\sigma$ determination of the CME rate per star, from which CME-driven atmospheric escape will be estimated.

ESCAPE's spectral coverage and spectral resolution ($\Delta\lambda < 1.5$ Å) are designed to spectrally isolate specific emission lines for temporally resolved lightcurve analysis over a range of coronal ionization states (Fe VIII–Fe XX). *ESCAPE* has the sensitivity to detect solar-like dimming events (6% max dimming depth in Fe IX 171 Å and Fe X 174 Å, summed over ten 30 minute exposures) to a distance of 6 pc. *ESCAPE* will survey 10 F, G, and K stars for solar-like CMEs as part of the DEEP survey. For these 10 F, G, and K stars, we expect *ESCAPE* will detect over 90 solar-like coronal dimming events. Therefore, *ESCAPE* will likely characterize the frequency of stellar CMEs for the first time. Deeper dimming events or those detectable in broadband spectral binning⁷¹ are even more readily detectable in *ESCAPE* time-series observations. We note that while dimming events from the hot coronae associated with very active stars may be detectable in the x-rays, EUV spectral coverage is required to sample the lower quiescent coronal emission temperatures typical of the more numerous, lower activity, planet hosting stars.

Magnetic fluxes on active M stars can be factors of 10 to 1000 times higher than global solar magnetic fluxes,^{91,92} potentially trapping the charged particle explosions associated with CMEs.⁹³ Simulations by our team indicate that CMEs with energy $> 10^{34}$ ergs will escape magnetic confinement from active M dwarfs and be detectable with *ESCAPE* (Jin et al. – in prep). *ESCAPE*'s observational capabilities enable us to search for EUV dimming signatures from M dwarfs for the first time, providing empirical constraints on the particle deposition into the atmospheres of orbiting planets.

6 Implementation: The ESCAPE Science Payload

The *ESCAPE* science mission requires measurements of the EUV and FUV fluxes of a sample of low-mass stars. To adequately carry out this program, *ESCAPE* must be at least 25-times more efficient across the 100 to 500 Å EUV band than any previous astrophysics spectrograph to operate in this range (EUVE DS/S; Bowyer and Malina, 1991,³⁰ Chandra LETG/HRC-S; Brinkman et al., 2000).⁹⁴ *ESCAPE*'s efficiency gain compared to previous missions is achieved with an instrument specifically designed to meet the *ESCAPE* objectives; i.e., optimized to be a cool star characterization instrument.

The *ESCAPE* telescope is the grazing incidence analog of a Gregorian [known as a Hettrick-Bowyer (HB), Hettrick and Bowyer],⁹⁵ with a 46-cm parabolic primary mirror, a prime focus aperture (PFA), and a re-focusing elliptical secondary. An accessible prime focus is a defining

feature of Gregorian telescopes, and one of the critical elements that enables the high efficiency of ESCAPE; the field-limiting PFA provides stray-light suppression without costly bandpass limiting filters or additional reflections that would be prohibitive to meeting the system throughput requirements. The telescope is provided by a joint NASA/Marshall Space Flight Center (MSFC) and Smithsonian Astrophysical Observatory (SAO) team. Figure 7 shows the ESCAPE telescope and science instrument with key components labeled.

The ESCAPE spectrograph intercepts the converging beam from the telescope with an array of etched silicon gratings supplied by Pennsylvania State University (PSU). The grating bank is divided into two channels to optimize performance over a broad EUV bandpass: the G20 (78 to 339 Å) and the G40 (94 to 564 Å; Table 1). The gratings are ruled with a quasi-radial groove pattern to maintain a constant linear dispersion. Each channel is divided into segments sized to be compatible with a standard 6 in. silicon wafer for ease of manufacture and heritage. Segments are co-aligned with the aid of an optical grating ruled onto a nominally unilluminated portion of the substrate.

The resulting spectra are curved in an arc-of-diffraction common in all radial groove spectrographs and recorded onto a microchannel plate (MCP) detector developed by the University of California, Berkeley (UCB) – the workhorse detector type for all EUV and FUV instruments. The zero-order reflections off of the G20 and G40 gratings are folded back onto two normal

Fig. 7 A schematic representation of the ESCAPE science instrument: a grazing incidence Gregorian telescope (Sec. 6.1.1) feeding a grazing incidence spectrograph (Sec. 6.1.2). The primary mirror diameter is 0.46 m and the end-to-end length of the instrument is ~ 2 m. Major components are labeled.

Table 1 ESCAPE spectroscopic modes.

Grating	Bandpass (Å)	Spatial resolution (μm)	Spectral resolution (Å)	Peak A_{eff} (cm^2)
G20	78 to 339	500	0.91 ^a	67.4
G40	94 to 564	500	0.65 ^a	35.2
G70	600 to 825	475	3.6 ^b	2.6
G140	1250 to 1650	475	6.1 ^b	4.5

^aEvaluated at 171 Å.

^bAverage resolution over the band.

incidence re-focusing gratings, the G70 (600 to 825 Å) and G140 (1250 to 1650 Å), to obtain long-wave EUV and FUV coverage. These spectra are recorded onto the same MCP detector as the grazing channels, providing this spectral coverage with minimal additional complexity. The ESCAPE instrument covers the required broad spectral range simultaneously with a fixed optical configuration that requires no mechanisms or bandpass limiting optics during normal science operations.

6.1 Instrument Subsystems

In the following sections, we describe the key components of the ESCAPE instrument in greater detail.

6.1.1 ESCAPE telescope

The ESCAPE telescope is a grazing incidence Gregorian with a prime focus point in between the primary and secondary mirrors (see Fig. 7; Hettrick and Bowyer).⁹⁵ The final architecture was chosen after a series of trade studies to maximize efficiency and minimize complexity.

The ESCAPE parabolic primary mirror is a 1-mm thick $\times$ 500-mm long, 46-cm maximum diameter nickel shell with a focus point at the PFA pinhole (500 μ m diameter). The PFA restricts the field-of-view of ESCAPE to a top-hat function with a 1.6 arcmin full-transmission zone and wings extending out to a 3.6-arcmin diameter. This restricted field-of-view limits geocoronal airglow in the system without requiring costly bandpass limiting transmission filters. The diverging beam is re-focused by a 1-mm thick $\times$ 152-mm long, 13-cm outer diameter elliptical secondary mirror.

The mirror shells will be fashioned at NASA/MSFC by electro-forming a nickel-cobalt alloy onto a super-polished aluminum mandrel figured to the desired optic prescription. This is known as electro-formed nickel replication, the same mirror technology used for IXPE, XMM-Newton, FOXSI, MaGIXS, and other NASA flight programs. Both telescope optics are coated with 20 nm of zirconium in the coating facilities at SAO (Romaine et al., 2011).⁹⁶ Zirconium has excellent performance at critical ESCAPE wavelengths and is widely used for thin film applications.

6.1.2 ESCAPE spectrograph

Grazing Incidence Gratings—the ESCAPE short-wavelength EUV channels utilize quasi-radial off-plane blazed gratings at grazing incidence.^{97,98} Each channel intercepts roughly half of the telescope power at average graze angles of $\theta = 11^\circ$ (G20) and 19° (G40). The groove patterns are angled to match the converging telescope rays to maintain a constant linear dispersion, increasing the groove density as the rays approach focus. Light is diffracted along an arc of diffraction, with spectra offset in the cross-dispersion direction. The bandpass of each channel is extended by leveraging multiple spectral orders. Higher spectral order contributions are suppressed by the telescope graze angles; all $m \geq 3$ order in G20 and $m \geq 4$ in G40 have effective area (A_{eff}) $< 0.5 \text{ cm}^2$.

The gratings are lithographically ruled into single crystal silicon wafers following a process developed by PSU under a NASA Strategic Astrophysics Technology (SAT) award⁹⁹ and demonstrated with ESCAPE grating prescriptions.¹⁰⁰ The wafers are cut from the parent boule so the $\langle 111 \rangle$ crystal plane orientation matches the desired blaze angles. This grating fabrication technique produces smooth and uniform blaze facets, maximizing diffraction efficiency while readily meeting the low scatter requirement of $I/I_o < 10^{-3}$ at 10 Å from an emission line to suppress scattered H I Ly α . The segments are diced to a rectangular form and bonded to kovar mounts with X, Y, and θ adjustment capability to aid in segment alignment.

Normal Incidence Gratings – The NI gratings are supplied by Horiba Jobin-Yvon; the normal incidence channels leverage unused detector area to provide essential science capability with minimal added complexity. The G70 and G140 channels consist of 14-mm square flat fold mirrors that pickoff the reflected zero-order light from the G40 and G20, respectively, and direct it to concave re-focusing holographic gratings. The spectra are imaged onto the same detector as the grazing incidence channels. The G140 channel is coated in MgF₂ protected aluminum, whereas

the G70 channel is coated in silicon carbide (SiC). The gratings are bonded to an aluminum support structure with manual tip/tilt adjustment for alignment. The fold mirrors are mounted on the detector support truss in a small enclosure to baffle stray light. A 4-mm thick, 6-mm diameter CaF₂ window intercepts the G140 beam to attenuate >95% of geocoronal H I Ly α .

6.1.3 ESCAPE detector system

The ESCAPE spectra are imaged by a 125 × 40 mm MCP detector system with mild focal plane curvature (0.5 m) and a cross delay line (XDL) readout anode. The baseline design uses borosilicate-glass MCPs activated by atomic layer deposition, which have flight heritage on large formats and with curvatures (DEUCE; Erickson et al., 2021,¹⁰¹ SISTINE; Cruz-Aguirre et al., 2021;¹⁰² JUNO-UVS; Davis et al., 2018).¹⁰³

UV light sensing is accomplished with an opaque KBr photocathode; a standard option for EUV and FUV missions (including EUVE and FUSE; Vallergera et al., Sahnou et al.).^{104,105} Consistent with previous flight detectors, we employ a charged 95% transmission grid to enhance the efficiency by collecting events that impinge on the detector face. The structure of this grid has been examined as part of the ESCAPE ray trace analysis and has been observed to have no noticeable impact on the PSF. The XDL readout anode is based on the SISTINE and DEUCE multilayer designs (France et al. 2016¹⁰⁶ and Erickson et al. 2021).¹⁰¹

ESCAPE utilizes an electronics package with flight heritage on numerous missions, including ICON-EUV, JUNO-UVS, JUICE-UVS, EUROPA-UVS, and EMM-EMUS.^{107–110} This package utilizes low-power amplifiers/discriminators for the start and stop signals of each axis of the XDL, followed by time to digital conversion, and an FPGA (ACTEL AX/RT family) to convert the raw event time of arrival differences into x and y and signal amplitudes outputted as 32-bit LVDS (13-bit X , 12-bit Y , and 7-bit pulse height). Maximum global count rates for primary science targets, including airglow contributions, are <1000 Hz, posing no counting rate challenges for the detector system.

6.2 Instrument Performance

The system effective area is a function of the reflection efficiency of the optics (R), efficiency of the gratings (ϵ_g), and quantum efficiency of the detector, multiplied by the geometric collecting area of the telescope (A_{geo}):

$$A_{\text{eff}}(\lambda) = A_{\text{geo}}R(\lambda, \theta)\epsilon_g(\lambda)DQE(\lambda). \quad (1)$$

The reflectivity of each optic is a function of the wavelength and graze angle, θ , which varies across the surface. To calculate this function, a grid of rays is traced through the system, with the graze angle at each optic intercept point used to calculate the power reflected as a function of wavelength. The rays are evenly spaced at the aperture to properly power-weight this function.

The total A_{eff} of ESCAPE (Fig. 8) is the sum of all diffraction orders, as well as the sum of the two GI channels for where the wavelength range overlaps. The A_{eff} of the NI channels (G70 and G140) is calculated with added terms for the fold mirror, CaF₂ filter (G140), and zero order reflection off of the corresponding GI grating.

The point-spread-function (PSF) is the sum of contributions from the intrinsic grating distortion, optical mount stresses, 1-sigma pointing jitter, maximum allowable mirror fabrication errors and maximum allowable detector resolution. This PSF produces a predicted RMS spectral resolution performance at 171 Å for the grazing incidence channels of 0.91 Å in G20 and 0.66 Å in G40 (second order), and normal incidence performance of 3.6 Å in G70 and 6.1 Å in G140 (see Table 1), averaged over the normal incidence mode bandpasses. The raytraced PSF spot for the G20 at 171 Å is shown in Fig. 9.

6.3 Simulated Data Example

We carried out science performance calculations using a conservative spot size corresponding to the baseline requirement of 1.5 Å spectral resolution at 171 Å, lower than the projected

Fig. 8 A comparison of the ESCAPE effective area (solid black line) compared with previous astrophysics missions covering the 100 to 912 Å EUV bandpass. ESCAPE intentionally introduces a gap in spectral coverage between ~550 and 600 Å to avoid strong O II and He I geocoronal emission.

Fig. 9 Projected PSF for the G20 mode at 171 Å, sampled at the detector digital pixel scale (~14 μm × 14 μm).

instrument performance. A simulated two-dimensional detector image of a SEEN survey target is shown in Fig. 10(a). ESCAPE's targets are cool stars, dominated by coronal and chromospheric line emission. Therefore, the order overlap associated with continuum sources that was an issue for EUVE is mitigated for ESCAPE and wavelength identification can be accomplished without wavelength blocking filters. For ESCAPE, the wavelength definition can be cleanly inferred from comparison of one-dimensional (1D) spectral extractions with solar or synthetic stellar spectra (as illustrated by the minimal spectral order overlap for solar-type stars shown in Fig. 10, center panels). More sophisticated forward modeling techniques, used on grating spectra at x-ray wavelengths (see, e.g., Brinkman et al.),⁹⁴ will be developed to identify spectral features by their location in the two-dimensional (2D) spectrogram.

Spectral data are order-sorted by three methods: (1) laboratory spectra obtained during instrument integration and testing provide a map of spectral detector locations as a function of input wavelength for known calibration gases, (2) on-orbit checkout calibration observations of cool stars with EUVE observations will be used to validate forward modeling analyses of coronal models; pre-flight simulations show clear delineation of different wavelengths in 1D spectral traces for G20 and G40 channels (Fig. 10, center), and (3) order-sorting filters (manufactured by Luxel) isolating short-, medium-, and long-wavelength EUV bands are well-established in solar missions and will be used to validate the forward modeling order sorting analysis as well as reject soft x-ray continuum leaking into the ESCAPE band for stars with high-temperature coronae.

An Al+Mg filter isolates the first order G40 spectrum (and supports the calculation of a predictive DEM model to guide the extraction). The G40 Open – Al+Mg difference spectra are

Fig. 10 A schematic representation of the ESCAPE science data flow for an inactive solar type star at a distance of 7 pc, with a typical SEEN exposure time of 35 ksec. (a) Level 3a science products contain the (λ, y, t) photon lists, including order identifications. The oval features are He II 304 Å airglow, which are spectrally isolated on the detector and do not impact the majority of the science spectrum. (b) 1D spectra are extracted and different wavelengths are readily identified in the G20 and G40 channels. (c) Order-sorted 1D spectra are combined with interstellar attenuation corrections and differential emission measure models to produce full extreme ultraviolet irradiance spectra.

cross-correlated with the Zr + MoSi₂ G20 spectra to isolate the first and second order G20 and G40 spectra. An indium filter tests for short-wavelength bremsstrahlung leaking into the ESCAPE band. Filters are only used for initial wavelength/order calibration activities; an open aperture position is used for all SEEN and DEEP survey observations.

Figure 10 shows the typical data flow for ESCAPE observations. The Level 2 products contain the instrument data organized by observations, photon lists at full detector resolution, with all of the detector related corrections applied (application of ground-based flat-field, thermal and geometric distortion maps, and 2D walk correction as necessary; e.g., COS Data Handbook 2015; France et al. 2011^[11]). The photon-list data are time-tagged to 100 msec accuracy.

Two Level 3 (L3) data products are generated: The L3a products preserve the full time-tag photon list from Level 2, with the addition of corresponding grating order probability (the fraction contributed by each order to the best-fit forward model spectrum at a given detector position) and wavelength for the four expected orders. Wavelength solutions are provided to the end-user for the creation of lightcurves in individual spectral features (as is done for HST-COS). Level 3a science products contain the $(\lambda, y, \text{ and } t)$ photon lists that are required for stellar flare and CME characterization [Fig. 10(a)]. L3b contain the fully calibrated, one dimensional spectrum in $\text{ergs cm}^{-2} \text{s}^{-1} \text{\AA}^{-1}$ as a function of wavelength (in Å) for each observation (both in individual orders and a final coadded spectrum). L3b data are combined with interstellar attenuation corrections and a DEM model to produce full extreme ultraviolet irradiance spectra [Fig. 10(b)]. The ESCAPE data will be hosted at the Mikulski Archive for Space Telescopes (MAST) archive.

Level 3a and 3b data products will be produced for individual exposures and exposure time integrated for each ESCAPE target to facilitate dissemination and use by the astronomical community. Level 3b science products contain the full 1D EUV and FUV stellar spectra that are required to measure and reconstruct the EUV irradiance incident on orbiting planets. Figure 4 shows a simulated SEEN observation (extracted counts spectrum) of the nearby planet-hosting M dwarf Proxima Cen, compared to an archival EUVE spectrum of the same source. Figure 11 shows a Level 3b data product of a simulated DEEP observation (the flux spectrum) of Proxima Cen and the predicted signal-to-noise ratio as a function of wavelength that includes the influence of local ISM absorption on the ESCAPE observations.

Fig. 11 (a) Simulated observation of the full EUV spectrum of Proxima Cen comparing the intrinsic (blue) and ISM-absorbed ESCAPE data (orange). (b) Signal-to-noise per 1.5 Å resolution element of a DEEP Survey observation of Proxima Cen.

7 ESCAPE Development Timeline

ESCAPE completed an initial Phase A study in mid-2021 but was not selected for full implementation. ESCAPE will be re-proposed to the next SMEX opportunity, presumably in ~2024. If ESCAPE is selected in that round, Phase B would begin in late 2025, culminating in the instrument and mission level preliminary design reviews in late 2026, respectively. Phase C includes comprehensive design review in late Q2 2027 and extends through August 2028. Phase D would run through the August 2029 launch and on-orbit commissioning. On-orbit spectral resolution tests are made by observing the unresolved and spectrally isolated Fe XIV and Fe XVI lines as these spectral diagnostics are expected to be present in all cool star observations (coronal line widths are <10% of instrumental resolution). Effective area as a function of wavelength is calibrated in flight by performing observations of well-studied hot white dwarf calibration stars. Phase E comprises the 20 month science mission when the full SEEN and DEEP surveys are executed; ESCAPE maintains a 26% mission lifetime margin to complete the baseline science mission.

Acknowledgments

The ESCAPE Phase A mission was managed at the Laboratory for Atmospheric and Space Physics at the University of Colorado Boulder under NASA contract No. 80GSFC21C0003. Portions of this manuscript appeared as SPIE proceeding 11821-001. The ESCAPE team acknowledges the numerous invaluable discussions with colleagues on the need for and approach to an EUV spectroscopy mission over the previous five years. In particular, KF thanks Alex Brown, Parke Loyd, and Tom Woods for enjoyable conversations on EUV spectroscopy and variability.

Kevin France is professor of astrophysical and planetary sciences at the University of Colorado. He is the PI of the ESCAPE Small Explorer mission, the CUTE small satellite mission, and a NASA-supported sounding rocket program to develop critical path hardware for future astrophysics missions. He is a regular guest observer with Hubble and member of the LUVOIR STDT. He received his PhD from Johns Hopkins University and was awarded NASA’s Nancy Grace Roman Fellowship.
