Abstract. I use Monte Carlo simulations and phantom measurements to characterize a probe with adjacent optical fibres for diffuse reflectance spectroscopy during stereotactic surgery in the brain. Simulations and measurements have been fitted to a modified Beer–Lambert model for light transport in order to be able to quantify chromophore content based on clinically measured spectra in brain tissue. It was found that it is important to take the impact of the light absorption into account when calculating the apparent optical path length, l_p , for the photons in order to get good estimates of the absorption coefficient, μ_a . The optical path length was found to be well fitted to the equation $l_p = a + b \ln(I_s) + c \ln(\mu_a) + d \ln(I_s) \ln(\mu_a)$, where I_s is the reflected light intensity for scattering alone (i.e., zero absorption). Although coefficients a – d calculated in this study are specific to the probe used here, the general form of the equation should be applicable to similar probes. © 2010 Society of Photo-Optical Instrumentation Engineers. Keywords: diffuse reflectance spectroscopy; brain; Monte Carlo simulations; chromophore quantification.

Paper 10190RR received Apr. 12, 2010; revised manuscript received Aug. 16, 2010; accepted for publication Aug. 19, 2010; published online Oct. 12, 2010.

1 Introduction

The brain is a most fascinating and complex organ, containing numerous chromophores such as blood, cytochromes, neuromelanin, and lipofuscin. The spectral profile of blood is highly dependent on the oxygenation level and the amount of cytochrome c oxidase reflects the activity of the tissue,¹ whereas melanin is characteristic to certain structures and the amount of lipofuscin is an indicator of tissue damage.² Stereotactic neurosurgery, such as implantation of deep brain stimulation (DBS) electrodes³ or radio-frequency lesioning (ablation),⁴ provides an opportunity to study these chromophores very locally, *in vivo*, and without adding any discomfort or risk to the patient, by the use of diffuse reflectance spectroscopy.^{5,6}

At the Department of Biomedical Engineering, Linköping University, probes have been developed for optical measurements in the brain during stereotactic neurosurgery. These have been used for optical studies with diffuse reflectance spectroscopy and laser Doppler flowmetry during creation of paths for DBS electrodes.^{5,7,8} These measurements, and those by others,^{6,9,10} have shown that the reflected light intensity at 780 nm can differentiate between gray matter, light gray matter (e.g., the thalamus), and white matter. The chromophore content has not yet been studied in detail, however. A difficulty with reflectance spectroscopy, compared to standard transmittance spectroscopy through thin samples, is that the apparent optical path length, l_p (in millimeters), is unknown

and varies with wavelength and tissue composition. An estimation of l_p is thus required in order to reliably analyze diffuse reflectance spectroscopy data.

Monte Carlo (MC) simulation¹¹ is a valuable tool for simulation of light transport in biological tissue. The technique utilizes random walk for a large number of photons and is considered as the gold standard for simulations in the field. MC simulations have for example been used to estimate l_p for transcranial near-infrared spectroscopy¹² and to calculate expected reflected intensity and look-ahead distance in brain tissue.^{13,14} Another method for solving the unknown path length is to use optical phantoms with known optical properties for inverse determination of the absorption and scattering coefficients in tissue.¹⁵ Such phantoms, spanning appropriate ranges of values for optical absorption and scattering, have been used for inverse determination of chromophore content in, e.g., the heart.¹⁶

The aim of this study is to develop an appropriate mathematical model for extraction of the absorption coefficients from intracerebral diffuse reflectance spectra, measured during DBS surgery. This will allow for determination of the chromophore content in the brain.

2 Material and Method

2.1 Probe and Spectroscopy System

The probe studied consist of a 190-mm-long metal tube with a diameter of 2.2 mm that decreases to 1.6 mm at the tip. It is used to create trajectories for DBS electrodes prior to their insertion. For spectroscopy, the probe contains two parallel,

Fig. 1 Geometry of the optical probe. The probe is 190 mm long and contains two adjacent optical fibers with a core diameter of 200 μm for spectroscopy. (It also contains two fibers for laser Doppler perfusion monitoring.)

adjacent optical fibers with a core diameter of 200 μm , a cladding diameter of 230 μm , and a numerical aperture of 0.22 (Fig. 1). The emitting fiber is connected to a white halogen lamp (AvaLight-Hal-S, Avantes BV, The Netherlands) and the receiving fiber to a spectrometer (AvaSpec-2048-2, Avantes BV, The Netherlands). The lamp contains a shutter that allows the light to be shuttered without turning it off. A white polytetrafluoreten reference tile (WS-2, Avantes BV, The Netherlands) is used to normalize the light intensity so that it only shows the characteristics of the illuminated tissue, not the sensitivity of the spectrometer or the intensity (I_0) of the lamp, which both are highly nonlinearly dependent on the wavelength.

2.2 Monte Carlo Simulations

The optical fibers of the probe were modeled as illuminating and viewing a homogeneous domain of brain tissue. Models were made for white and gray matter at wavelengths between 480 and 900 nm. The scattering coefficients, μ_s (mm^{-1}), and anisotropy factors, g ; were taken from human *ex vivo* data¹⁷ (see Table 1). The Henyey–Greenstein phase function¹⁸ was used to randomize scattering angles based on g . From the simulations, a pure scattering intensity, I_s ; was calculated as

$$I_s = \sum_i I_{s,i}, \quad (1)$$

where $I_{s,i}$ is the component from simulated photon number i . Absorption was not calculated in the simulations but added during postprocessing according to the Beer–Lambert law to simulate the reflected light intensity,

$$I = \sum_i I_{s,i} e^{-l_{p,i} \mu_a}, \quad (2)$$

where $l_{p,i}$ is the simulated optical path length for photon number i and μ_a the absorption coefficient. For each simulation, μ_a was included according to Eq. (2) in doubling steps between 0.01 and 2.56 mm^{-1} , with the assumption that each simulated photon represents a large number of real photons and not a discrete quantum. In total, 12 simulations were made, giving 12 values of I_s and 12×8 values of I for the different combinations of I_s and μ_a . The simulated intensity for white matter at 780 nm and $\mu_a = 0.08 \text{ mm}^{-1}$ was used as reference level, defining the intensity here as 1. In each simu-

Table 1 Used optical properties for MC simulations and corresponding μ'_s .

Tissue	Wavelength (nm)	μ_s (mm^{-1})	g	n	μ'_s (mm^{-1})

lation, 5×10^6 photons were used. Software developed at the Department of Biomedical Engineering, Linköping University, was used for the simulations.¹⁹

2.3 Fitting of Scattering Intensity and Apparent Optical Path Length

I_s and μ'_s for gray and white matter were fitted, using the Levenberg–Marquardt algorithm, to the expression $\alpha \cdot \lambda^{-\beta}$, where α and β are fitted coefficients. This relation is generally used for the reduced scattering coefficient of biological scatterers in the visible and near-infrared range.²⁰ Matlab 7.9 (Mathworks Inc., Natick, Massachusetts, USA) was used for the fitting. Weighted errors, E , for the fits were calculated according to

$$E = \frac{\hat{x} - x}{x}, \quad (3)$$

where $\hat{x}$ is the fitted value of variable x .

With I_s and I calculated from Eqs. (1) and (2), an apparent optical path length, l_p , was calculated as

$$l_p = \frac{\ln(I_s) - \ln(I)}{\mu_a}. \quad (4)$$

Equation (4) is based on Beer–Lambert law modifications by Jacques et al.^{15,21} but I_s and l_p was not assumed to be polynomials of the reduced scattering coefficient, $\mu'_s = \mu_s \cdot (1 - g)$, as l_p also is affected by μ_a .²² Instead, the apparent optical path length from the simulations were plotted against I_s and μ_a in order to determine a more appropriate fit, $l_p(I_s, \mu_a)$.

2.4 Phantom Measurements

Twenty-five phantoms consisting of ultrahigh temperature-treated (UHT) milk (1.5% fat, Arla Foods, Sweden), water-soluble blue ink (Coloris, Germany), and water were created. Milk concentrations were varied in steps of 20% between 20 and 100%, and the ink was added in doubling concentrations between 1/4000 and 1/250, corresponding to peak absorption values from 0.23 to 3.67 mm⁻¹.²³ The milk was assumed to be a purely scattering medium and the ink a purely absorbing medium. One row of phantoms without ink was also made in order to provide measurements of the pure scattering spectra, I_s . Diffuse reflectance spectroscopy measurements were performed with the optical brain probe in random order, at room temperature, on the same day as the phantoms were created. Normalized spectra were calculated by

$$I = \frac{I_{\text{raw}} - I_{\text{dark}}}{I_{\text{cal}} - I_{\text{dark}}}, \quad (5)$$

where I_{raw} is the raw spectrum measured from the phantom, I_{cal} a white spectrum measured against the white reference tile, and I_{dark} a dark spectrum measured with all light shuttered.

A reference simulation of the reflected light intensity at 780 nm for UHT milk was made in order to provide a reference level for the intensity. The ink was diluted to 10% in order to ease the mixing process. However, this causes minor fluctuations in milk concentration between the phantoms. In

order to compensate for this, I_s from the inkless phantom with the same milk concentration was scaled for each ink-containing phantom so that its intensity between 815 and 900 nm was equal to the intensity, I , from the phantom. The scaling factor was taken as the mean I between 815 and 900 nm divided by the mean I_s between 815 and 900 nm.

As for the results from the simulations, a regression model for l_p was made. Only the intensity at the peak absorption wavelength (633 nm) of the ink was used for the regression here though.

2.5 Application on Clinical Data

Finally, the method obtained from the simulations and phantom measurements was tested on two spectra from cortical gray matter and subcortical white matter, obtained during DBS surgery in an earlier study.⁵ As for the phantom measurements, I was calculated with Eq. (5) and the mean intensity at 780 nm from subcortical white matter was used to define $I = 1$. After thoroughly cleaning the optical fibers, white and dark spectra had been obtained right after the surgery without turning off the lamp or disconnecting the probe in between.

Using linear regression, the calculated absorption spectra were fitted to chromophores that can be expected to be found in the brain: Deoxyhaemoglobin,²⁴ oxyhaemoglobin,²⁴ lipofuscin,²⁵ eumelanin,²⁶ and reduced and oxidized forms of cytochromes c and aa3.^{27–29} If any chromophore yielded a negative regression coefficient, then the chromophore with the largest negative coefficient was removed and the regression was redone.

3 Results

3.1 MC Simulations

The fits of the reduced scattering coefficient used for the simulations were proportional to $\lambda^{-0.96}$ for gray matter (mean $E^2=0.0027$) and to $\lambda^{-1.16}$ for white matter (mean $E^2=0.0046$). The corresponding fits to I_s were proportional to $\lambda^{-1.03}$ for gray matter (mean $E^2=0.0019$) and $\lambda^{-0.80}$ for white matter (mean $E^2=0.0035$). There was an obvious curvature of the residuals versus wavelength for I_s from white matter though, and it was found to fit better to a linear decrease with wavelength (mean $E^2=0.0002$). A linear regression in the range 780–900 nm, where μ_a can be assumed to be low or at least approximately constant, was thus assumed for I_s in white matter [Fig. 2(a)] I_s increased linearly with μ'_s for gray matter but nonlinearly with the higher μ'_s for white matter [Fig. 2(b)]. Simulated I_s ($\mu_a=0$ mm⁻¹) was $\sim 4\%$ higher than simulated I from gray matter at $\mu_a=0.02$ mm⁻¹ and $\sim 10\%$ higher than simulated I from white matter at $\mu_a=0.08$ mm⁻¹. The simulations thus indicate that I_s should be $\sim 7\%$ higher than measured I in average for brain tissue.

By plotting l_p versus the variables I_s and μ_a , it was found that a logarithmic transformation of the variables gave a fairly linear relation (Fig. 3). The following regression model was thus fitted:

Fig. 2 (a) Intensity, I , versus wavelength for pure scattering white matter, i.e., I_s in white matter, (•), white matter with $\mu_a = 0.08 \text{ mm}^{-1}$ (◊), pure scattering gray matter, i.e., I_s in gray matter, (+) and gray matter with $\mu_a = 0.02 \text{ mm}^{-1}$ (○). The absorption values are typical in brain matter for λ between 580 and 900 nm at negligible blood content.¹⁷ In a real spectrum, the intensity will be much lower beneath 600 nm due to absorption from, e.g., blood (see Fig. 1). I_s decreases linearly with λ for white matter while it is approximately proportional to λ^{-1} for gray matter. (b) I_s versus the reduced scattering coefficient, μ_s' .

$$I_p = a + b \ln(I_s) + c \ln(\mu_a) + d \ln(I_s) \ln(\mu_a), \quad (6)$$

where coefficients a – d are presented in Table 2 together with the goodness of fit, R^2 , of the regression model. Equations (4) and (6) gives the estimate of μ_a according to

$$\mu_a [a + b \ln(I_s)] + \mu_a \ln(\mu_a) [c + d \ln(I_s)] = \ln(I_s) - \ln(I), \quad (7)$$

if the intensity due to scattering alone is assumed to be known. Equation (7) can then be solved numerically with a starting point for μ_a close to zero, because the equation also will have another solution for higher μ_a . The latter should be discarded because it will be outside the range of values used to obtain the model. The numerical solving of Eq. (7) was performed using Matlab. Fitting errors when using Eq. (7) with the coefficients from the simulations on the simulation results are presented in Fig. 4(a) (mean $E^2 = 0.0015$).

3.2 Phantoms

From the MC simulation of the milk, the intensity level was calculated to 0.38 of white matter intensity at 780 nm for pure

milk. Examples of reflectance spectra from the phantoms are presented in Fig. 5(a).

When applying Eq. (7) to the reflectance spectra from the phantoms, a decent fit of μ_a was found for the highest ink concentrations but lower concentrations yielded overestimations, which were higher for the lower the ink concentration [Figs. 5(b) and 4(c)]. Fitting the results at 633 nm (peak absorption) from the phantoms to Eq. (6) yielded coefficients b and c with higher magnitude (Table 2). Fitting errors when using the coefficients from the phantoms on the phantom results are presented in Fig. 4(b) (mean $E^2 = 0.0040$).

3.3 Clinical Data

On the basis of the simulations and phantom measurements, the following method was used to calculate the absorption coefficient in brain tissue based on a measurement with the optical probe:

1. Calculate a linear regression against λ^{-1} for gray matter or λ for white matter from the brain spectrum in the interval 780–900 nm and extrapolate it downward in wavelength to 480 nm in order to obtain I_s .
2. Scale I_s by a factor 1.04 for gray matter or 1.1 for white matter in order to compensate for the nonzero absorption in

Fig. 3 Apparent optical path length for different values of I_s and μ_a plotted versus the logarithms of (a) I_s and (b) μ_a . MC simulations were performed for gray and white matter at wavelengths between 480 and 900 nm. For each simulation, absorption was added during postprocessing in doubling steps between 0.01 and 2.56 mm^{-1} , giving a 12×8 matrix of results.

Table 2 Coefficients for Eqs. (4) and (5) and corresponding goodness of fit, R^2 .

Coefficient	From MC simulations	From phantom measurements
a	0.813	0.838
b	−0.198	−0.298
c	−0.145	−0.289
d	0.0522	0.0377
R^2 (%)	99.1	96.2

Fig. 4 Weighted errors, $E = (\hat{x} - x)/x$, when Eq. (6) is used to estimate μ_a (a) when the coefficients from the simulations are used on the results from the simulations, (b) when the coefficients from the phantoms are used on the phantoms, and (c) when the coefficients from the simulations are used on the phantoms.

the interval 780–900 nm. Solve Eq. (7) numerically for each wavelength in the interval 480–900 nm using the coefficients a – d obtained from the simulations or phantom measurements in order to obtain the absorption coefficient spectrum.

3. Fit the spectra of known chromophores, as described earlier, to the calculated absorption spectrum by the use of linear regression with the constraint that no chromophore concentration can be negative.

The reflectance and resulting absorption coefficient spectra are presented in Fig. 6 for cortical gray matter and in Fig. 7 for subcortical white matter together with regression fitting of the chromophores. The major chromophores for cortical gray matter in these fits were lipofuscin, corresponding to an unknown concentration, and deoxyhaemoglobin, corresponding to a deoxygenated blood volume fraction of 0.54%, while lesser contributions were estimated for melanin, corresponding to a melanosome volume fraction of 0.08%, and the reduced forms of cytochromes c and $aa3$, corresponding to concentrations of 2.2 and 4.0 μM , respectively [Fig. 6(b)]. The major fitted chromophores for the subcortical white matter

[Fig. 7(b)] were melanin (0.11% melanosomes) and lipofuscin (unknown concentration). Lesser contributions were estimated to be from oxyhaemoglobin (0.12% oxygenated blood), deoxyhaemoglobin (0.14% deoxygenated blood), and oxidized cytochrome $aa3$ (2.4 μM).

4 Discussion

In this study, a method for estimation of the absorption coefficient in brain tissue based on diffuse reflectance spectra has been developed. The coefficients a – d in Eqs. (6) and (7) are depending on the fiber configuration and are thus not directly applicable to other optical probes. The equations should however be valid, in general, and could be used for similar probes if the corresponding coefficients are estimated for them.

A reliable estimate of μ_a is important if reliable quantification of the chromophores in the tissue is to be achieved. Chromophores that could be of interest to quantify are, e.g., oxy- and deoxyhaemoglobin, lipofuscin, neuromelanin, and cytochromes. Haemoglobin content can give information

Fig. 5 (a) Reflectance spectra from milk phantoms (100% milk) with ink amounts that should correspond to peak absorption coefficients of, from up to down, 0, i.e., I_s (black), 0.23 (green), 0.46 (blue), 0.92 (red), 1.84 (cyan), and 3.67 mm^{-1} (magenta). (b) Corresponding calculated absorption coefficients normalized to an ink concentration that ideally should result in a peak absorption of 1.84 mm^{-1} . The dotted black line represents absorption measured with collimated transmission spectroscopy.²³ The calculated absorption is higher than it should be for the lower ink concentrations. (Color online only.)

Fig. 6 (a) Reflectance spectrum, I , from human *in vivo* cortical gray brain tissue together with estimated pure scattering spectrum, I_s . (b) Absorption coefficient, calculated by Eq. (6) with coefficients from the phantom measurements, for this spectrum together with fitted chromophore spectra for the absorption. According to this fit, the biggest contribution to the absorption comes from deoxyhaemoglobin and lipofuscin. Lesser contributions are estimated to be from melanin and the reduced forms of cytochromes c and aa3. Particularly notable is the apparent lack of oxyhaemoglobin.

about blood volume in the tissue. Caution should be taken regarding this when using an invasive probe, such as the one investigated in this study, because it is likely to affect the blood distribution in the tissue when inserted. The pressure from the insertion could press out blood from the vessels in the tissue, and bleeding could cause the presence of blood between the probe and the tissue. The estimated blood concentrations of 0.54% in the cortex and 0.36% in the white matter in this study are a lot lower than values from positron emission tomography (PET) studies of 5.5 ± 0.6 ml/100 g and 2.1 ± 0.56 ml/100 g, respectively, which should equal the percentage under the approximation that 1 ml tissue has a mass of 1 g. Some of the difference could also be explained by the short fiber distance, which usually only will view the microvascular blood fraction, though. Haemoglobin content can also give the tissue blood oxygen saturation by calculating the ratio of oxygenated to total blood volume fraction. The example in this paper of an *in vivo* spectrum from the brain

cortex shows a surprising lack of oxyhaemoglobin. Why this is and whether this is common in the brain would be of great interest to investigate further. According to PET studies, the oxygen extraction fraction in brain tissue should be $\sim 40\%$,³⁰ thus, an oxygen saturation $\sim 60\%$ would be expected in this case, assuming the probe primarily views venous microvascular blood. One possible contribution to this discrepancy could be arteriovenous shunting, which has been indicated in dog brain, especially during hypercapnia.³¹ If some arterial blood is shunted directly to the veins without delivering oxygen to the tissue, then it could cause the venous blood to have higher oxygen content than the microvascular blood.

Lipofuscin is a common chromophore that is usually overlooked in the field of biomedical optics. It consists of biological garbage that the lysosomes of the cells have not been able to digest and it accumulates with age in long-lived cells that undergo little or no cell division (e.g., neurons and cardiac and skeletal myocytes). A high amount of lipofuscin indicates

Fig. 7 (a) Reflectance spectrum, I , from human *in vivo* subcortical white brain tissue together with estimated pure scattering spectrum, I_s . (b) Absorption coefficient, calculated by Eq. (6) with coefficients from the phantom measurements, for this spectrum together with fitted chromophore spectra for the absorption. According to this fit, the biggest contribution to the absorption comes from melanin and lipofuscin while lesser contributions comes from oxy- and deoxyhaemoglobin. A very minor contribution is also attributed to oxidized cytochrome aa3.

high oxidative damage, is also likely to further hamper digestion of damaged structures, and adds more oxidative damage.² Neuromelanin exists in certain structures of the brain (e.g., the substantia nigra). The substantia nigra lies just beneath the subthalamic nucleus (STN), which is a common target for DBS,³² and the presence of melanin in a measured spectrum could thus indicate a too deep position for a DBS electrode that is supposed to be in the STN. Cytochromes c and aa3 (a.k.a. cytochrome c oxidase) are important components for the generation of adenosine triphosphate in the mitochondria, and cytochrome aa3 concentration is indicative of how active the neurons are.¹ In this study's cortex spectrum, the concentrations for cytochromes c and aa3 were estimated to 2.2 and 4.0 μM , respectively. Navarro et al.³³ have made *in vitro* measurements of cytochrome c and aa3 concentrations in human frontal cortex. In Parkinsonian brains, they found a mitochondrial concentration of 11.8 ± 0.4 mg protein/g brain cortex and cytochrome concentrations of 0.23 ± 0.02 nmol/mg mitochondrial protein and 0.17 ± 0.01 nmol/mg mitochondrial protein for cytochromes c and aa3, respectively. Assuming that 1 g brain cortex equals 1 ml, this should correspond to volume concentrations of ~ 2.6 μM for cytochrome c and 2.0 μM for cytochrome aa3.

The simulated I_s for gray brain matter was found to be proportional to λ^{-1} . The reduced scattering coefficients used for the brain matter simulations (Table 1) were also approximately proportional to λ^{-1} . I_s for white brain matter was better described by a linear relation to wavelength, however. The reason for the difference can be seen in Fig. 2(b): I_s increases linearly with μ'_s for the lower values in gray matter, but the increase is slowed down for the higher values in white matter. The behavior of myelin-rich light gray matter, such as the globus pallidus or the lateral part of the thalamus, can unfortunately not be determined by this, but it seems reasonable to expect that it will behave as a mixture of gray and white matter.

The modeling is based on a single fiber distance because that is the kind of probe that we currently use in the brain. It would be beneficial to include at least one larger fiber separation in order to get more reliable estimates of I_s . Such a setup would allow for more objective separation of the effect of scattering and absorption on the reflected intensity because the relative impact of scattering and absorption is different for different source-detector separations.³⁴ It will be particularly difficult to distinguish between melanin content and potential errors in the estimation of I_s when using just one fiber separation, because melanin has a smoothly decreasing absorption curve that neither has any characteristic peaks nor can be assumed to be zero anywhere in the spectral range 480–900 nm. This limitation is probably less severe for tissue that does not contain melanin. Melanin in the cortex spectra could be expected if the melanin-containing leptomeninges³⁵ (arachnoidea and pia mater) are pushed ahead of the probe a bit. The fitting of melanin to white matter in Fig. 7(b) is dubious though, and the fit also includes a baseline term that is difficult to explain. It is always possible that the absorption coefficients used in the simulations are too high and that I_s should be closer to I in the infrared range. This could be suspected based on the very flat residual spectra in Figs. 6(b) and 7(b). It is also possible that there is some

Table 3 Comparison of absorption coefficient, μ_a , to *in vitro* values from literature.

unknown chromophore absorbing infrared light. Absorption from lipid³⁶ and water is often included when using near-infrared spectroscopy with large fiber distances, but because their μ_a is <0.01 mm^{-1} in the range 600–900 nm, they should be negligible here. What could be of interest to investigate, however, is whether myelin, whose abundance causes the high μ'_s in white matter, has any noticeable absorption in the visible and near-infrared range.

Comparing to *in vitro* data (Table 3), the μ_a spectrum for white matter calculated by Yaroslavsky et al.¹⁷ from measurements on human *in vitro* samples has a low-varying level of ~ 0.08 mm^{-1} above 500 nm and does not show any obvious melanin content. Their samples were rinsed from blood prior to measurements, and consequently, their spectra show little influence from blood absorption. Their gray matter spectrum show a more evident decrease in absorption with wavelength in the visible range. A similar tendency can be seen in spectra by Gebhart et al.,³⁷ with the biggest difference that blood still is present in their spectra.

It is important to note that μ_a has an effect on I_p that in no way is negligible compared to the effect of scattering. The effect of μ_a on I_p has nevertheless often been omitted in studies when estimating μ_a by a modified Beer–Lambert law.^{21,38,39} Using a light transport model such as Eq. (6) should greatly improve the estimates of I_p and thus also the estimates of μ_a . Matcher et al.⁴⁰ have, e.g., pointed out that the impact of μ_a on I_p dampens higher absorption coefficients compared to lower ones, which is in agreement with the negative value of coefficient c obtained in this study. The tendency for Eq. (7) to overestimate low μ_a indicates that the impact of μ_a on I_p actually is greater than implied by the simulations, as can be

seen by the greater magnitude of coefficient c obtained from the phantom measurements. The coefficients from the phantom measurements are probably more reliable than those from the simulations as the latter may be affected by errors in the MC model assumptions regarding, e.g., geometry, phase function, and fiber characteristics. There are possible errors with the phantoms, too, though. Although assumed to be purely absorbing, the ink used seems to have a small scattering component, which probably is causing some overestimation of its μ_a . Similarly, there is probably some absorption in the milk itself. Also, I_s from pure UHT milk is lower than from white brain matter and the phantoms thus do not cover the entire range of interest. A more scattering liquid, such as Intralipid,⁴¹ might provide a better base for the phantoms.

It can be seen in Figs. 3 and 4(a) that the apparent optical path length, l_p , is not completely linearly dependent on the logarithms of the absorption and pure scattering intensity. Higher order terms could thus be added in order to get more accurate modeling. This may be worthwhile if more fibers at further distances are added. The greater slope on the lower I_s values also indicates that the magnitude of coefficient c from the phantoms may be too high for white matter because the higher white matter intensities are not covered by the phantom intensities. In particular, one should be very cautious if I_s and μ_a are very high because Eq. (6) then can give negative, and thus unphysical, estimates of the optical path length. That could happen if a blood vessel is ruptured for example.

In conclusion, the proposed method will give an approximate quantitative measurement of the absorption coefficient and should thus allow for quantification of chromophores in the brain. This study also elucidates the importance of taking the impact of the absorption coefficient into account when estimating the apparent photon path lengths.

Acknowledgments

The author thanks his colleague Tobias Lindbergh, for valuable tips and discussion. The study was supported by NovaMedTech (funded by the European Union and Tillväxtverket, the Swedish Agency for Economic Growth), the Swedish Governmental Agency for Innovation Systems (Vinnova), the Swedish Foundation for Strategic Research (SSF), and the Swedish Research Council (VR, Dnr. 311-2006-7661).
