Abstract. The aim of this study was to investigate the effects of inner and heard speech on cerebral hemodynamics and oxygenation in the anterior prefrontal cortex (PFC) using functional near-infrared spectroscopy and to test whether potential effects were caused by alterations in the arterial carbon dioxide pressure (PaCO_2). Twenty-nine healthy adult volunteers performed six different tasks of inner and heard speech according to a randomized crossover design. During the tasks, we generally found a decrease in PaCO_2 (only for inner speech), tissue oxygen saturation (StO_2), oxyhemoglobin ($[\text{O}_2\text{Hb}]$), total hemoglobin ($[\text{tHb}]$) concentration and an increase in deoxyhemoglobin concentration ($[\text{HHb}]$). Furthermore, we found significant relations between changes in $[\text{O}_2\text{Hb}]$, $[\text{HHb}]$, $[\text{tHb}]$, or StO_2 and the participants' age, the baseline $\text{P}_{\text{ET}}\text{CO}_2$, or certain speech tasks. We conclude that changes in breathing during the tasks led to lower PaCO_2 (hypocapnia) for inner speech. During heard speech, no significant changes in PaCO_2 occurred, but the decreases in StO_2 , $[\text{O}_2\text{Hb}]$, and $[\text{tHb}]$ suggest that changes in PaCO_2 were also involved here. Different verse types (hexameter and alliteration) led to different changes in $[\text{tHb}]$, implying different brain activations. In conclusion, StO_2 , $[\text{O}_2\text{Hb}]$, $[\text{HHb}]$, and $[\text{tHb}]$ are affected by interplay of both PaCO_2 reactivity and functional brain activity. © The Authors. 1 Introduction

Previous studies of guided rhythmic speech exercises in the context of arts speech therapy (AST) on human physiology showed that AST tasks, i.e., recitations, are associated with characteristic changes in variations in the heart rate^{1,2} and cardiorespiratory interaction. In a next step, effects on cerebral and systemic changes of hemodynamics and oxygenation were investigated by our research group using functional near-infrared spectroscopy (fNIRS).^{3,4} A decrease in cerebral hemodynamics and oxygenation was found to occur during speech exercises, which was hypothesized to be a result of a decrease in the partial pressure of carbon dioxide (CO_2) in the arterial blood (PaCO_2) during speaking. This hypothesis was confirmed in a subsequent study combining fNIRS and capnography,⁵ where we observed changes in end-tidal CO_2 ($\text{P}_{\text{ET}}\text{CO}_2$), a reliable and accurate estimate of PaCO_2 ,^{6–8} during all speech tasks and even during the control task (mental arithmetic). This led us to conclude that the changes in hemodynamics and oxygenation are a combination of two factors: (1) a hypercapnia mediated by changes in breathing (hyperventilation) during the tasks and (2) changes in brain activity (neurovascular coupling), where previously the first factor was probably stronger than the second one.

In a following study,⁹ we demonstrated that even inner speech, i.e., speech not spoken aloud, leads to significant

changes in $\text{P}_{\text{ET}}\text{CO}_2$ as well as cerebral hemodynamics and oxygenation. Table 1 gives an overview of previous study results.

These results triggered the question of whether simply hearing a recitation also causes changes in PaCO_2 and, thus, in cerebral hemodynamics and oxygenation. Since this question had not been addressed yet, but is of importance in functional studies involving speech, the aim of the present study was to investigate the effect of different types of (1) inner speech and (2) heard speech on $\text{P}_{\text{ET}}\text{CO}_2$ dynamics as well as cerebral hemodynamics and oxygenation measured using fNIRS and capnography.

2 Materials and Methods

2.1 Subjects, Experimental Protocol, and Instrumentation

Twenty-nine healthy subjects (14 men, 15 women, mean age: 47.0 ± 12.8 years) participated in this study, which was carried out as a controlled and randomized crossover trial. Study participants were German/Swiss German native speakers who had no previous knowledge of AST and were asked not to smoke, eat, or consume any stimulants (such as caffeine or other ingredients in energy drinks) for at least 2 h before the start of the measurements. Approval for the study was obtained from the Ethical Committee of the Canton of Zurich: the design of the study was in accordance with the Declaration of Helsinki and informed consent was obtained from the subjects prior to each measurement.

Table 1 Listing of study details.

Reference	Experimental protocol	Results
1	$N = 15$, age: 44 ± 10 years, task: rhythmic speech, rest. Measured parameters: HRR, HRV	Speech-induced changes in HRR, HRV, and cardiorespiratory interaction
2	$N = 20$, age: 43 ± 6.6 years, tasks: hexameter recitation (H), controlled breathing (C), and spontaneous breathing (S). Measured parameters: HRV	Strength of cardiorespiratory synchronization: $H > C > S$
4	$N = 7$, age: 29 to 49 years, task: hexameter recitation (H). Measured parameters at PFC and calf muscle: StO_2 , $[O_2Hb]$, $[HHb]$, $[tHb]$	PFC (during H): $StO_2 \downarrow$, $[O_2Hb] \downarrow$, $[tHb] \downarrow$ CM (during H): $[tHb] \downarrow$, $[HHb] \downarrow$
3	$N = 17$, age: 35.6 ± 12.7 years, tasks: recitation of hexameter (H), alliteration (A), or prose (P). Measured parameters at PFC and calf muscle: StO_2 , $[O_2Hb]$, $[HHb]$, $[tHb]$	PFC (during all tasks): $StO_2 \downarrow$, $[O_2Hb] \downarrow$ CM (during all tasks): $[O_2Hb] \uparrow$, $[tHb] \uparrow$
5	$N = 24$, age: 22 ± 6.4 years, tasks: mental arithmetic (M), recitation of hexameter (H), alliteration (A), or prose (P). Measured parameters: (i) PFC: StO_2 , $[O_2Hb]$, $[HHb]$, $[tHb]$; (ii) $P_{ET}CO_2$	During all tasks: $P_{ET}CO_2 \downarrow$ PFC (during H, A, P): $StO_2 \downarrow$, $[O_2Hb] \downarrow$, $[HHb] \uparrow$, $[tHb] \downarrow$ PFC (during M): $StO_2 \uparrow$, $[HHb] \uparrow$
9	$N = 7$, age: 34.9 ± 9.3 years, tasks: inner mental arithmetic (iM), inner recitation of hexameter (iH), or prose (iP). Measured parameter: (i) PFC: StO_2 , $[O_2Hb]$, $[HHb]$, $[tHb]$; (ii) $P_{ET}CO_2$	During all tasks: $P_{ET}CO_2 \downarrow$ PFC (during iH, iP): $StO_2 \downarrow$, $[O_2Hb] \downarrow$ PFC (during M): $StO_2 \downarrow$

Note: HRR, heart rate rhythmicity; HRV, heart rate variability; CM, calf muscle; PFC, prefrontal cortex.

Three task modalities were applied: (1) inner recitation of the text (inner speech, IS), and listening to the text (heard speech, HS) while (2) the text was recited by a person (HSP), or (3) a recorded recitation was played (HSR). Two different types of text were used, i.e., one with hexameter and one with alliterative verses. Thus, six different tasks were investigated: inner speech of a (1) hexameter (IS-H) and (2) alliterative (IS-A) text, listening to a live recited (3) hexameter (HSP-H) and (4) alliterative (HSP-A) text, and listening to a recorded (5) hexameter (HSR-H) and (6) alliterative (HSR-A) recitation.

The two text types have the following characteristics: alliteration is a form of rhythmic speech with repetition of a particular initial sound in the first syllables of a series of words or phrases; the hexameter is a metrical line of verse consisting of six feet. These two verse types induce a different flow of speech and may induce different patterns of brain activity. Alliteration and hexameter recitation were investigated in this study since they are frequently used in the context of AST. Recitation of a person was applied because it closely resembles the situation in AST; recorded recitation was additionally employed because it ensures the same recitation for every participant.

Each measurement lasted 43 min [8 min baseline (interval 1), 5 min task (interval 2), 5 min recovery (interval 3), 5 min task (interval 4), and 20 min recovery (intervals 5 to 8)]. To avoid potential carry-over effects, each task was performed on a separate day. During the IS and HSP tasks, the subjects sat opposite a person who recited the respective text verse-by-verse. During the HSR tasks, the subjects sat opposite two speakers (LS11, Logitech Inc., Fremont, USA) and the prerecorded recitation (performed by the same person who recited during the IS and HSP tasks) of the texts was played. The recitations were recorded using an electret condenser microphone (ECIMF8, Sony, Japan) and the open-source software Audacity (<http://audacity.sourceforge.net>). In order to improve sound quality, the recorded recitations were denoised, normalized, and equalized by Audacity. The recorded recitation was played at such

a volume that at the position of the subject (directly in front of his face), the sound level was 65 dBA on average, which was measured using a sound meter (320, Voltcraft, Hirschau, Germany). Also during the HSP condition, the sound level was 65 dBA on average.

As in the previous study,⁵ the following physiological parameters were measured: (1) StO_2 and absolute concentrations of $[O_2Hb]$, $[HHb]$, and $[tHb]$ (device: ISS OxiplexTS frequency-domain NIR spectrometer, sampling rate: 50 Hz) and (2) $P_{ET}CO_2$ (devices: Nellcor N1000 and Datex NORMOCAP capnograph).

The OxiplexTS optodes were placed on the left and right side of the forehead over the prefrontal cortex (PFC) at Fp1-F3/Fp2-F4 according to the international 10–20 system.¹⁰ The PFC has been chosen because it constitutes a region of the brain that has been demonstrated to be activated in language processing,¹¹ speech production,¹² semantic processing, and phonological/lexical processing,^{13,14} and also easily allows for fNIRS measurements with a high signal-to-noise ratio due to the absence of absorbing hair in this region of the head.

The $P_{ET}CO_2$ probe was positioned directly below the right nostril of the subject. A visualization of the placement of the NIRS optode, the CO_2 sensor, and a schematic representation of the NIRS optode can be found in Fig. 1. For a detailed description of the ISS OxiplexTS frequency-domain NIR spectrometer specifications, please refer to Ref. 5. Absolute values of StO_2 , $[O_2Hb]$, $[HHb]$, and $[tHb]$ were calculated by the OxiplexTS software using the frequency-domain multidistance (FDMD) method, which enables sensitivity to the extracerebral tissue to be reduced.^{15,16} This methodological approach is superior to the traditional modified Beer-Lambert method in excluding extracranial hemodynamic changes.¹⁷ The FDMD method calculates the following slopes: (1) the amplitude slope (S_{AC}), i.e., $\ln(d^2 U_{AC})$ versus d , where d is the distance and U_{AC} is the amplitude of the light intensity, and (2) the phase slope (S_{ϕ}), i.e., ϕ versus d , where ϕ is the phase shift of the light. From S_{AC} and S_{ϕ} the absorption coefficient was determined using the equation

Fig. 1 (a) Schematic representation of the near-infrared spectroscopy (NIRS) optode with respective source detector distances. (b) The placement of NIRS optodes at the Fp1-F3 and Fp2-F4 positions according to the international 10-20-system and the CO₂ sensor in the nostril.

$$\mu_a = \frac{\omega}{2v} \left(\frac{S_\varphi}{S_{AC}} - \frac{S_{AC}}{S_\varphi} \right)$$

with v the speed of light in the tissue and ω the angular modulation frequency of the source intensity. Based on the μ_a at 690 and 830 nm and using the molar extinction coefficients for O₂Hb and HHb, the concentrations of O₂Hb and HHb were calculated in a subsequent step (for the equations, please refer to Ref. 5).

2.2 Signal Processing and Statistical Analysis

Signal processing was performed using MATLAB® (version 2008b, The Mathworks, Natick, MA). Movement artifacts in StO₂, [O₂Hb], [HHb], and [tHb] were removed using the method presented in Ref. 18 after successful application in previous studies^{3,5,19-25} and positively evaluated in a recent analysis comparing different movement artifact correction techniques for fNIRS.²⁶ Care was taken to ensure that no artificial new trends were introduced to the signals while applying the algorithm.

The P_{ET}CO₂ values were calculated directly from the capnography waveform signal by detecting the peaks of each breath cycle using a method recently developed in-house²⁷ and by interpolating the peaks by a piecewise cubic interpolation to form a continuous signal.

Each time series was segmented into intervals with a length of 3 min each, covering the time intervals 4 to 7, 9 to 12, 14 to 17, 19 to 22, 24 to 27, 29 to 32, 34 to 38, and 39 to 42 min. For further analysis, all signals were downsampled to 5 Hz and the fNIRS-derived signals were low-pass filtered using a moving average filter (window length: 10 s). For all signals, median values of each interval were calculated and normalized by subtracting the median value of the first interval. Statistical analysis was performed using SPSS software (version 20.0, IBM Corp., Armonk, NY). It was tested whether (1) the interval median values have a distribution with a zero median (Wilcoxon test), (2) the changes in the left PFC are different from those in the right PFC (Wilcoxon paired test), (3) the six types of tasks cause significantly different changes (Kruskal-Wallis test), and (4) the two types of recitation texts (hexameter and alliteration) are associated with different changes in the signals (Mann-Whitney-U test). For all tests we calculated the raw p -values and also applied the Benjamini-Hochberg correction²⁸ to account for the multiple comparison situation.

Additionally, data of the present and two previous own studies with equal design^{5,9} were combined. To test for significant relations between changes in cerebral hemodynamics and oxygenation and the different speech tasks, linear regression analyses were calculated with a stepwise procedure for each StO₂, [O₂Hb], [HHb], and [tHb] as the dependent variable and age, gender, body mass index, side of measurement (right or left PFC), baseline P_{ET}CO₂, and the various speech tasks as the covariates.

3 Results

Figure 2 reports the changes in StO₂, [O₂Hb], [HHb], and [tHb] at the right and left PFC for the six different tasks. Figure 3(a) shows the changes in P_{ET}CO₂ for all tasks. A change induced by a task was considered significant when a significant, i.e., $p < 0.05$, change occurred in interval 2 or interval 4 or in both.

Qualitative summary of the results are as follows (for significances, see Figs. 2 and 3): (1) During the tasks (i.e., intervals 2 and/or 4): P_{ET}CO₂ decreased significantly only during IS-H and IS-A. StO₂, [O₂Hb], and [tHb] showed generally a decrease and [HHb] an increase at both PFCs. (2) During the recovery period (i.e., intervals 5 to 8): StO₂, [O₂Hb], and [tHb] showed generally an increase and [HHb] a decrease at both PFCs.

The changes (during the task and during the recovery period) in StO₂ and [HHb] were statistically significantly different between the right and left PFC (Benjamini-Hochberg corrected) for the HSR-A task. StO₂ generally decreased (and [HHb] increased) more strongly at the right PFC compared to the left PFC, reaching statistically significant changes for the HSR-A task.

The test of different dynamic behaviors of the signals over the right and left PFC when combining all tasks performed in the present study showed statistically significant differences. The comparison of the changes with respect to the two different speech types (hexameter versus alliteration) showed that for the left PFC, statistically significant differences in changes occurred for [tHb] during and after the task, and for [O₂Hb], after the task. The right PFC showed no differences; also P_{ET}CO₂ was not different for the two types of tasks.

The test of differences in changes for all tasks and signals revealed only the P_{ET}CO₂ changes in the recovery period were statistically different when comparing HSP-A and HSR-A. When comparing hexameter and alliteration tasks, the changes in [tHb] at the left PFC during tasks and after them were statistically different.

Fig. 2 Changes in StO_2 , $[\text{O}_2\text{Hb}]$, $[\text{HHb}]$, and $[\text{tHb}]$ over the course of the experiments. Each interval refers to a time span of 3 min. The shaded areas indicate the periods when the tasks were performed. All data are shown as median values (black circles) $\pm$ standard error of the median ($\text{SE}_{\text{median}} = \text{MAD}/n^{0.5}$, where MAD is the median absolute deviation and n is the number of measurements). Significant changes are marked with an asterisk: $p < 0.05$ (*). Corrected significant p -values (according to the Benjamini-Hochberg correction) are marked with two vertically aligned asterisks.

Fig. 3 (a) Changes in P_{ETCO_2} over the course of the experiments. Each interval refers to a time span of 3 min. The shaded areas indicate the periods when the tasks were performed. All data are shown as median values (black circles) $\pm$ standard error of the median ($SE_{median} = MAD/n^{0.5}$, where MAD is the median absolute deviation and n is the number of measurements). Significant changes are marked with an asterisk: $p < 0.05$ (*). Corrected significant p -values (according to the Benjamini-Hochberg correction) are marked with two vertically aligned asterisks. During the task, significant changes were only found for inner speech. (b) Scatter plots showing the relationships between changes in P_{ETCO_2} and $[tHb]$ (from right prefrontal cortex: black circles; from left prefrontal cortex: black dots) depending on the specific task conditions.

Linear regression analyses revealed several significant relations between changes in $[O_2Hb]$, $[HHb]$, $[tHb]$, or StO_2 and the participants' age, the baseline P_{ETCO_2} , or certain speech tasks (see Table 2).

The participants' age influenced changes in cerebral hemodynamics and oxygenation. With increasing age, the decreases in StO_2 , $[O_2Hb]$, and $[tHb]$ during the tasks (interval 4) were less pronounced. This significant relation largely vanished when only participants below the age of 50 were included in the analyses (not shown). We also found that compared to younger subjects, older subjects had a lower $[O_2Hb]$ and $[HHb]$ value in the baseline period (interval 1).

The recitations of hexameter or alliteration verses aloud had no significant relations with any of the dependent variables, in contrast to mental arithmetic, inner speech, or listening to hexameter or alliteration verses. Hexameter verses affected changes during the tasks (interval 4), while alliteration verses only affected changes during the recovery phase (interval 7).

Figure 4, illustrated by the inner recitation tasks, shows that the changes in P_{ETCO_2} appear quite early after the start of the tasks.

4 Discussion

4.1 Measured Changes in End-Tidal CO_2 , Cerebral Hemodynamics, and Oxygenation

In order to explain the observed cerebral hemodynamic and oxygenation changes obtained from the studies involving speech tasks, two major physiological processes should be considered:⁵ neurovascular coupling (NC) and CO_2 reactivity (CO_2R).

NC occurs due to increased neuronal activity leading to an increase in the cerebral metabolic rate of O_2 , resulting in an increase in cerebral blood flow (CBF) and thus volume (CBV).^{29,30} This effect causes the following characteristic changes of the fNIRS signals: increase in $[O_2Hb]$, decrease in $[HHb]$, and increase in $[tHb]$ and StO_2 .

CO_2R describes the effect of changes in CBF and CBV in response to changes in $PaCO_2$, mediated by a cerebral vasoconstriction or vasodilation. Changes in $PaCO_2$ have a strong and robust effect on cerebral hemodynamics, i.e., an increase in the frequency and/or breathing volume (hyperventilation) causes a decrease in $PaCO_2$ (hypocapnia), which leads to a reduction in CBF by cerebral vasoconstriction.^{31,32} This effect results in the following characteristic changes of the fNIRS signals: decrease in $[O_2Hb]$, increase in $[HHb]$, and decrease in $[tHb]$ and StO_2 .

Regarding the results obtained from the present study, the questions arises whether one of the two effects mentioned was prevailing or whether they were caused by a combination of both. The decrease generally found in StO_2 , $[O_2Hb]$, and $[tHb]$ as well as the increase in $[HHb]$ during all six interventions may at first glance be interpreted as if the NC was overpowered by the CO_2R , i.e., a hyperventilation induced hypocapnia, which causes a cerebral vasoconstriction as the main effect. However, our results show that the relationships between changes in P_{ETCO_2} and hemodynamics and oxygenation are not linear [see Fig. 3(b)]. If the hypocapnia was the sole relevant effect, we would expect linear relationships (at least in the first approximation) as demonstrated by other investigations.³³ But in the present study, a task evoking a significantly higher change in P_{ETCO_2} compared to another task is not

Fig. 4 Block average (median of all subjects and two tasks) of the P_{ETCO_2} changes for inner recitation of hexameter and alliteration. Shown are the median values (thick blue line), standard error of the median (light blue error bars), and a trend (smoothing of the median values, span: 30 s, thick red line).

accompanied by a larger change in tHb [see Fig. 3(b)]. In addition, the response of the cerebral blood vessels to changes in $P_{ET}CO_2$ is known to be robust and much stronger than other physiological parameters, such as oxygenation or blood pressure. Thus, even a small change in $P_{ET}CO_2$, which does not reach significance in our results, may have a relevant and significant effect on cerebral hemodynamics.³⁴ For both reasons, the observed effects in hemodynamics and oxygenation cannot solely be explained by a hypercapnia. Thus, we consider a combination of NC and CO_2R . The NC characteristics are task-dependent, i.e., they counteract the CO_2R to different degrees leading to an apparent nonlinearity between $P_{ET}CO_2$ and hemodynamics/oxygenation. As already indicated in Ref. 9, it is reasonable that the different speech tasks are associated with different characteristics of brain activity. It is, for example, known that mainly stress^{35–37} and specific types of cognitive processes (particularly memory retrieval and multitasking)³⁸ are modulating factors for the activity of the PFC. Thus, we deem it likely that two overlapping and counterbalancing effects (NC and CO_2R) are causal in our study, where the strength of each effect appears to be task-dependent. For inner speech and heard speech (person) of a hexameter, the CO_2R was quite different, yet the changes in StO_2 were the same. This indicates that the NC during inner speech was stronger and counteracted the CO_2R stronger, which therefore resulted in similar changes in StO_2 . We also would expect that inner speech, which includes hearing and reciting the verses, necessitates a more pronounced effort than simply hearing the verses and, consequently, leads to larger brain activation. This is in line with the results of the measurements, and thus, it appears to be reasonable to assume that the effects elicited by speech cannot be explained by the CO_2R alone.

For a visualization of the interplay between NC and CO_2R during a speech task, please refer to Fig. 4 in Ref. 5. The observation from this figure that $P_{ET}CO_2$ changes quite early after the start of the tasks indicates that changes in $P_{ET}CO_2$ can also be elicited during relatively short task intervals—a fact that might be relevant for all experimental protocols involving speech task in general.

The increase of StO_2 and $[O_2Hb]$ in the postbaseline period after the tasks (i.e., intervals 5 to 8) (see Fig. 2) cannot simply be explained by a change in regional CBF (rCBF) due to relaxation and entering a state of consciousness on the transition to sleep since a reduction of rCBF in the PFC was found during light sleep,³⁹ which would lead to a decrease in StO_2 and $[O_2Hb]$.

The finding that hexameter verses influenced changes during the tasks (interval 4) and alliteration verses only influenced changes during the recovery phase (interval 7) (see Fig. 2) suggests that the different flow of speech of these verses might induce different patterns in brain activity and different dynamics of the interplay between NC and CO_2R .

The results obtained by the present study are in general agreement with a previous fNIRS speech study. We demonstrated that inner speech (recitation of hexameter and prose) induces a CO_2R associated with characteristic changes in cerebral hemodynamics and oxygenation.⁹ The nonlinearity between $P_{ET}CO_2$ changes and changes in the fNIRS parameters was also observed and attributed to a task-dependent intensity of the brain activity and thus NC. In an fNIRS study involving reading aloud as a task, Fallgatter et al.⁴⁰ observed a decrease in $[O_2Hb]$ and an increase in $[HHb]$, which is in line with our observation. We are not aware of functional magnetic resonance

imaging (fMRI) studies with a similar study design as in our study. Studies investigating language processing and speech production, e.g., Refs. 11 and 12, reported changes in the blood-oxygen-level-dependent (BOLD) signal but not if these changes reflect an actual increase or decrease in hemodynamics/oxygenation. In general, the comparison of fMRI and fNIRS results is also not straight forward since the CO_2R depends on the specific type of tissue compartment and characteristic (arterial, venous, arterio-venous, small versus large vessel radius),⁴¹ and since fMRI and fNIRS are sensitive to different tissue structures: fNIRS is sensitive to the microvasculature comprising arterioles, venules, and capillaries, i.e., small vessels,⁴² whereas fMRI is more sensitive to larger vessels⁴³ and especially, large draining veins.⁴⁴ Because the CO_2R is especially high in arterioles and venules,⁴¹ fNIRS seems generally to be more sensitive to task-evoked CO_2 changes compared to fMRI.

A novel finding of the present study is that even simply hearing speech causes a weak and often not significant change in $P_{ET}CO_2$, partly interfering with NC and thus leading to changes in fNIRS signals that were not expected when not considering CO_2R and only NC as the cause of the observed changes.

The generally stronger decrease in StO_2 and increase in $[HHb]$ observed at the right PFC compared to the left PFC during the speech tasks may indicate that the task-related NC in the left PFC is stronger than in the right PFC, counterbalancing the CO_2R effect. This conclusion is in agreement with fMRI findings that overt and inner speech cause a left-hemispheric dominance of activity in the PFC.⁴⁵ A higher activity in the left part of the cortex was also observed by fNIRS.⁴⁶ A dichotic listening test revealed hemispheric lateralization of speech sound perception, where the largest $[O_2Hb]$ increase and $[HHb]$ decrease was found in left superior temporal gyrus. Furthermore, Ref. 47 found in an fMRI study involving a word generation task a maximum brain activity in the left hemisphere, mainly in the frontal lobe (Broca's area, premotor cortex, and dorsolateral PFC).

The large intersubject variability of the analyzed signals in our study is in agreement with findings in numerous other fNIRS studies (e.g., Refs. 48–51). However, on the group level, fNIRS studies provide reproducible results.⁵²

When interpreting our results it would also be worth considering systemic changes that might have interfered with the two main effects (NC and CO_2R): (1) changes in the activity state of the autonomic nervous system (ANS), which have an influence on cerebral hemodynamics and oxygenation,^{53–55} and (2) changes in mean blood pressure (MBP).^{56,57} However, our fNIRS signals are reasonably immune regarding superficial MBP changes (due to the FDMD method used),¹⁵ and the cerebral autoregulation in healthy adult subjects is expected to reduce the effect of systemic MBP changes on cerebral hemodynamics. However, due to the transient changes in $P_{ET}CO_2$ during the tasks (see Fig. 4), cerebral autoregulation might not remain unaffected, and thus the fNIRS signals might also contain a component originating from MBP changes. Further studies should investigate this aspect more closely.

In addition to the results of the present study, when analyzing our last three studies (i.e., the present study and the studies reported in Refs. 5 and 9) combined using regression models, we found significant relations between the participants' age as well as baseline (i.e., interval 1) $P_{ET}CO_2$ and the changes

in $[O_2Hb]$, $[HHb]$, and $[tHb]$ during and after the tasks. It is known that elderly subjects have lower resting-state cerebral $[O_2Hb]$, $[HHb]$, and $[tHb]$ (Ref. 58) and show less activation in the motor or PFCs in motor or verbal fluency tasks, respectively.^{59–62} Age-related diminished changes in cerebral hemodynamics and oxygenation ($[O_2Hb]$ and $[HHb]$) in response to hypoxia (breath holding) found by Ref. 63 were in agreement with our results since the observed hypocapnia in our study is associated with a mild cerebral hypoxia. An age-related decrease in resting-state CBF was also shown in studies using arterial spin labeling,⁶⁴ positron emission tomography,^{65–68} and single photon emission computed tomography.⁶⁹

Regarding the observed significant relation between the baseline $P_{ET}CO_2$ values and the changes in cerebral hemodynamics and oxygenation during and after the tasks, similar effects were found in other studies. For example, Blockley et al.⁷⁰ showed that the amplitude of the fMRI BOLD response depends on the baseline physiological state (hematocrit, oxygen extraction fraction, and CBV) of the subject. Other studies demonstrated that the magnitude of the BOLD response^{71,72} and the strength of neural activity^{73,74} depend on the $PaCO_2$ level.

Regarding possible confounding factors in our study design, two factors should be discussed: (1) possible different characteristics and (2) different personal perception of the texts. We controlled for the first factor by choosing texts with similar substance and emotional content. Concerning the second factor, we reduced its influence by measuring a large number of subjects and thus compensating for personal differences.

4.2 Implications for Further Research on the Topic

The results obtained in the present study and the combined analysis of our last three studies with regression models allow four implications to be drawn for further research on the topic: (1) The impact of changes in $PaCO_2$ should be considered in the interpretation of fNIRS studies involving speech tasks, including audible, inner, and even heard speech. (2) The use of capnography in combination with fNIRS is recommended. (3) Signal processing techniques should be developed and applied to distinguish between CO_2R -related and NC-related changes in fNIRS signals. (4) In order to investigate the influence of the ANS state on the fNIRS signals, the measurement and analysis of skin conductance and heart rate variability changes during speech tasks might also be important for a proper interpretation of fNIRS signals. In addition, measurements of MBP changes in future studies would contribute to interpreting the fNIRS results.

In conclusion, we found that changes in brain activation and breathing during different speech tasks affected cerebral hemodynamics and oxygenation. We showed that inner speech causes changes in $PaCO_2$, which have an impact on cerebral hemodynamics and oxygenation. A new finding is that even during heard speech, a CO_2R takes place, leading to characteristic changes in cerebral hemodynamics and oxygenation. In the left PFC, we found a significant difference between the alliteration and hexameter verses. Our analysis also showed that hexameter verses influenced changes during the tasks, while alliteration verses influenced changes only during the recovery phase, indicating that the two different types of verses seem to evoke different physiological reactions. Furthermore, we found significant relations between changes in $[O_2Hb]$, $[HHb]$, $[tHb]$, or StO_2 and the participants' age, the baseline $P_{ET}CO_2$, or certain speech tasks.

To the best of our knowledge, the present study is the first to investigate the impact of $PaCO_2$ changes on cerebral hemodynamics and oxygenation during speech listening tasks measured with fNIRS and capnography simultaneously. We highlight that the measurement of $P_{ET}CO_2$ during functional speech tasks appears to be an important parameter for reliable and correct interpretation when using fNIRS. Thus, we recommend that $P_{ET}CO_2$ changes be measured in future fNIRS and possibly also fMRI neuroscientific studies involving speech tasks.

Acknowledgments

The authors like to express their gratitude to all subjects who participated in this study and the arts speech therapist Andrea Klapproth for valuable advice regarding the speech tasks. For proofreading of the manuscript we thank Rachel Scholkmann.
